Introduction

Chemical degradation of glass-based materials is often considered unimportant, mainly due to the fact, that glass is generally perceived as very durable material. Highly corrosion resistant glass-based materials are utilized as coatings (glazes and enamels) for corrosion protection of less durable materials, notably metals. They also serve as inert matrices for storing dangerous waste, both chemical or radioactive. On the other hand, degradation of glass, either through direct corrosion in various environments (e.g., dishwashing in large gastronomy, as the most palpable example), or weathering when exposed to elements, causes significant losses to glass producers and users. Leaching of components of glass to liquid content stored in container glass vessels might impair the safety of food, beverages, and above all drugs and medicals. Controlled dissolution of some specific glass compositions facilitates its use in the human body as a biomaterial, replacing both hard (bones) and soft (cartilage) tissues. All these applications require a deep understanding of the mechanisms responsible for glass degradation, and detailed knowledge of the influence of glass composition and structure on its dissolution in various agents, at a molecular level.

Corrosion

All materials in contact with various types of environments show a certain degree of interaction. Interactions resulting in the degradation of mechanical and physical properties or appearance of a material have a negative impact on the usability of the material in the long run. Corrosion can therefore be defined as physical and chemical changes in a material caused by interactions with the environment in which the material is used. For the three main groups of materials, i.e., metals, glass (including ceramics), and polymers, the degradation mechanisms differ. Unlike metals, glass is perceived as chemically highly resistant at low temperatures ($<100^{\circ}\text{C}$), and corrosion occurs mostly at elevated temperatures or in contact with aggressive, mostly aqueous, environments.

The term glass corrosion is then applied for a complex interaction between a glass surface and a corrosive medium (in most cases an aqueous solution). As a consequence, irreversible changes both to glass and to the solution occur.

Corrosion can be classified using several parameters: the way of the attack, the site of the attack, and the medium in which the material is used or to which it is exposed. The classification of individual parameters is schematically shown in [Table 1](#) (Nickel, 1997).

Basic classification of the type of corrosion distinguishes between active and passive corrosion. In the active form, a glass in contact with the corrosive environment is gradually lost, by dissolving in a liquid corrosion environment which is accompanied by a change in the size and weight of the sample.

The passive form involves processes where the glass reacts with a corrosive environment to form a new condensed phase covering its surface. Weight gain or positive change in sample size is observed. The new phase can slow down the corrosion process over time (surface passivation), but there are also cases where the newly formed layer does not prevent further attack of the corrosive medium (Riedel, 2000).

In terms of location of the corrosion attack, the glass, as a phase-homogeneous material, is characterized by external corrosion, where the surface is usually attacked evenly, and the material is either evenly dissolved or a uniform layer of corrosive products is formed. The process becomes more complex if grain boundaries or a secondary phase in the form of finely dispersed particles (e.g., in glass-ceramics)

Table 1 Classification schemes of corrosion

Weight and volume change	Negative	Active corrosion	
	Positive	Passive corrosion (layer of corrosion products is formed)	Slows down corrosion (protective role) Does not affect corrosion rate
Physical-chemical conditions of corrosion medium	Solution (e.g., acid)		
	Melt	Metal Ionic liquid	Hot corrosion Salts/slugs Silicate melts
	Gas		Hot gas corrosion
Location of the corrosion attack	Whole surface		
	Localized	Random places Secondary phases Grain boundaries	

are present in the material, each phase reacting differently with the environment: in this case, localized attack and uneven corrosion of the glass matrix may occur.

Significant differences in the corrosion behavior of individual materials are caused by the variability of the corrosive environment. Corrosive behavior is thus not a property of the material as such, but that of the whole system material – corrosive medium. Therefore, there exists no standard, generally applicable procedure to evaluate the corrosive behavior of glass, just as it is not possible to devise a generally applicable corrosion mechanism to glasses of various compositions and exposed to various environments. The chemical resistance of glass is thus affected by the glass itself and the conditions to which the glass is exposed. The procedures for evaluation of various types of glass under various conditions are specified in a number of norms and standards (DIN 52289: 1998–09, 1998; DIN-EN 12875–2, 2002; ISO 10629:1996, 1996; ISO 20492:2008, 2008; ISO, 4794:1982, 1982; ISO, 8424:1996, 1996).

Corrosion Media

The variability of corrosive environments is so large that any attempts to classify corrosion behavior entirely from the point of view of the individual environment were bound to fail. The most commonly used scheme classifies the corrosive media according to their physical state. Relatively large attention has been paid to the corrosion of various types of materials in hot gases, but this environment is usually irrelevant for the corrosion of glass. Ambient air, which is relevant for the degradation of glass by weathering, is also a corrosive environment. In this case, the primary corrosive agent is moisture containing dissolved oxygen, but sulfur compounds (SO_2 , SO_3) and sodium chloride, which is often present in the air, especially in coastal areas, also contribute to corrosion. A diluted sulfuric acid solution in the form of acid rain is a source of corrosion in industrial areas.

The most relevant and most frequently investigated media for glass corrosion are liquids, i.e., aqueous solutions (acids, bases or solutions of inorganic salts), (Callister, 2005; Tressler and McNallan, 1990; Schilm *et al.*, 2007). In terms of its corrosion characteristics, the aqueous environment is extremely diverse. Natural water usually contains dissolved oxygen and other minerals, some of which determine the hardness of the water. Seawater is generally more aggressive than freshwater, containing approximately 3.5 wt% of salts (mainly sodium chloride) as well as some other minerals and organic substances (Herrmann *et al.*, 2000).

Thermodynamic Equilibrium in the System Glass-Liquid

Chemical thermodynamics deals with chemical changes that take place in a system glass-liquid corrosion medium, such as changes in the composition of the corrosive medium, changes in the molar amount of the individual components in the system as a result of chemical reactions, and transitions of the components between phases, and the composition of the corrosive medium after reaching equilibrium.

All chemical reactions tend to reach equilibrium, i.e., each system tries to reach the state with the lowest energy, which is accompanied by a decrease in the value of the total Gibbs energy G of the system. The Gibbs energy is then a function of the extent of the reaction ξ , i.e., $G = G(\xi)$. The Gibbs energy of any substance or phase in a system depends on a number of factors, temperature, pressure, and composition, in particular. This dependence is described by Eq. (1) (Stumm and Morgan, 1996; Oelkers *et al.*, 2009):

$$dG = Vdp - SdT + \sum_{i=1}^k \mu_i dn_i \quad (1)$$

where V is volume, p is pressure, S is entropy, T is thermodynamic temperature and μ_i and n_i represent the chemical potential and concentration of the i -th component, respectively. If we consider a system at a constant temperature and pressure, the first two terms on the right side of the equation are equal to zero. From the mass balance equations, it applies that $dn_i = v_i d\xi$. Then:

$$\left(\frac{\partial G}{\partial \xi}\right)_{T,p} = \sum_{i=1}^k v_i \mu_i = \Delta_r G_m, \quad (2)$$

where v_i represents the stoichiometric coefficient of component i . The equilibrium state of the system, i.e., the state with the smallest value of Gibbs energy, is characterized by the equilibrium value of the extent of the reaction $\xi = \xi_{\text{eq}}$, for which $\Delta_r G_m = 0$.

To illustrate the dissolution of a glass containing components B, where B represents cationic components, and A stands for anionic components, we can use, similarly to the dissolution of ionic compounds or minerals, a dissociation reaction (Eq. 3):

Where indices s and aq represent solid and liquid phases, respectively. The distribution of components in equilibrium can be then described as follows:

$$K_c = \frac{a(B_{aq}^{n+})a(A_{aq}^{n-})}{a_{BA}} \quad (4)$$

where a_i is the activity of the respective ion in solution and a_{BA} is the activity of the solid phase. Based on the definition of the

standard state, the activity of the solid phase is equal to 1; K_c is then equal to the solubility product K_s . In the case of a substance with complex stoichiometry, the equilibrium constant is generally expressed as $K = \prod a_i^{v_i}$, where v_i is the stoichiometric coefficient of the ion i in the formula of the solid. When we replace the chemical potential μ_i with the activity a_i , the expression for the Gibbs energy change takes the form:

$$\Delta_r G_m = \sum_{i=1}^k v_i \mu_i^o + RT \ln \prod_{i=1}^k a_i^{v_i} \quad (5)$$

where the first term on the right side of the equation represents the standard Gibbs energy. The activity of the components i in the system at a certain moment is expressed by the quantity Q , defined as $Q = \prod_i a_i^{v_i}$.

After reaching equilibrium, when $\Delta_r G_m = 0$, the numerical value of Q is identical with the equilibrium constant K . Then:

$$\Delta G_m^o = -RT \ln K \quad (6)$$

$$\Delta_r G_m = RT \ln \frac{Q}{K} \quad (7)$$

Comparing the values of Q and K provides information on whether the system is unsaturated ($\Delta_r G_m < 0$, the glass dissolves in liquid medium), in equilibrium ($\Delta_r G_m = 0$), or supersaturated ($\Delta_r G_m > 0$), and precipitation of reaction products at glass surface if favored, Schott *et al.* (2009).

The thermodynamic approach to the chemical durability of glass is based on a thermodynamic description of the solution with dissolved constituents of glass. We can define the Gibbs energy of formation of glass from elements G_{GL} as a difference between the Gibbs energy of formation of isocompositional polycrystalline system G_C and G_{vit} – the energy difference between the polycrystalline and the vitreous state. If we denote the energy state of an aqueous system containing dissolved glass constituents G_{GLaq} , we obtain the driving force of glass corrosion as ΔG_{hydr}

$$\Delta G_{hydr} = G_{GLaq} - G_{GL} \quad (8)$$

where the value ΔG_{hydr} is the quantitative representation of glass durability (Conradt, 2018). In terms of thermodynamic states, the glass corrosion at temperature T can be described by the sequence $\text{Glass}(T) + \text{aq.soln.}(T) \rightarrow \text{aq.species}(T)$ (Conradt *et al.*, 1999). The quantity ΔG_{hydr} is then influenced by the composition of glass, the energies of the formation of glass and its aqueous solution, and the temperature dependencies of the associated processes.

The rate of glass dissolution is influenced by temperature. According to Arrhenius Eq. (9), the rate constant changes with temperature exponentially:

$$k = A \cdot \exp\left(-\frac{E_A}{RT}\right) \quad (9)$$

where k is the reaction rate constant, and A is the empirical pre-exponential factor. The overall dissolution of glass is usually described through the dissolution of the rate-controlling species, which in silicate glasses is usually silica. Silicon atoms have to pass through an energetically unfavorable transient state, creating an activated complex characterized by the activation energy E_A . The activation energy represents the energy barrier that must be overcome for dissolution to occur. By logarithmizing the expression (Eq. 9) takes the form (Eq. 10):

$$\ln k = \ln A - E_A/RT \quad (10)$$

The $\ln k$ dependence on $1/T$ is linear, with the slope defined by (Eq. 11):

$$\frac{d \log k}{d(1/T)} = \frac{-E_A}{2.303R} \quad (11)$$

Diffusion processes in the liquid phase are characterized by low E_A values in the range of a few kJ mol^{-1} . The values in the range of about 80 kJ mol^{-1} are typical for surface reactions, while values of several hundred kJ mol^{-1} are associated with recrystallization processes (White, 1992). Based on the determined values of activation energies, we can infer the dissolution mechanisms. Some typical values of activation energies for chemical and transport processes are given in Table 2 (Appelo and Postma, 2005).

Table 2 Values of activation energies for chemical transport processes related to glass dissolution

Process	E_a (kJ mol^{-1})
Photochemical reactions	15 (10–30)
Diffusion in water	20
Dissolution and precipitation	60 (20–80)
Biochemical reactions	63 (50–75)
Solid state diffusion	500 (200–650)

Fig. 1 Curves describing the rate of ion transfer into solution for different dissolution mechanisms. (A) Solid equilibrates with the solution when the saturation concentration of C_s is achieved. (B) Linear kinetic dependence interrupted by formation of a precipitated phase. (C) Diffusion controlled (parabolic) dissolution kinetics. (D) Dissolution slowed by the formation of a precipitated phase.

Kinetics of Glass Corrosion

When modeling the kinetics of the corrosion process and determining the kinetic constants, we usually assume a steady-state and constant activity of the corrosion factor in the environment and an infinite amount of corroded material. A corrosion rate is then defined as a loss of matter per surface area and time.

The transport of ions from the glass to the solution can be schematically described by the curves shown in Fig. 1. If the glass is in contact with the corrosion medium, it gradually becomes saturated with respect to the content of the ionic components. The amount of dissolved material and the concentration of dissolved components increase with time. The dissolution rate slows over time and stops when the concentration of dissolved components reaches an equilibrium concentration. Heterogeneous and homogeneous reactions take place at the glass-corrosion medium interface. Any such reaction is characterized by the following steps:

- (1) Transport of reactants to the surface of the solid.
- (2) Adsorption of reactants.
- (3) Chemical reactions between adsorbed components and surface.
- (4) Desorption of reaction products.
- (5) Transport of reaction products into the volume of the corrosive medium.

The dissolution rate itself can be quantified according to the type of rate-controlling process. These are usually classified as follows (Giess, 1963; Sharp *et al.*, 1966; Berehta, 1984):

- (1) Film diffusion control (reaction rate controlled by the flow velocity of the solution),
- (2) Surface control (rate control by an energy barrier, e.g., an activated complex, in the surface),
- (3) Pore diffusion control (rate control by diffusion through a growing layer),
- (4) Nucleation and crystallization rate control (i.e., the formation of a new secondary phase in the vicinity of the dissolving phase).

During active corrosion under steady-state conditions, the material is lost by decomposition or dissolution. The flow of mass from corroded material can be expressed by Eq. (8):

$$J = k_r c_i \quad (12)$$

where J is the mass flow, k_r the reaction coefficient, and c_i the concentration of dissolved component i at the interface. For first-order reactions under steady-state conditions, the dependence is linear. The diffusion-controlled kinetics is then described by Fick's first law. At equilibrium, the concentration gradient does not change, the thickness of the diffusion layer remains constant, and the

flow J is also constant. The weight loss (Δx) of the dissolving material will change linearly with time t :

$$\Delta x = k_t t \quad (13)$$

where k_t is the rate constant (g s^{-1}).

In the case of passive corrosion accompanied by the formation of a layer of reaction products, the situation is more complex. A more or less porous layer of precipitated or re-mineralized secondary phases forms on top of the residual glass. The layer either acts as a diffusion barrier or controls the elemental concentrations in the solution at the interface to the residual glass. In the simplest case, the corrosion is controlled by chemical reaction. If the reaction proceeds slowly compared to the flow of reagents to the reaction site, the concentration of solute at the interface is as high as its concentration in the surrounding corrosive medium. In this case, for a given temperature, the linear time dependence of the mass change is observed, following Eq. (13). The term Δx is positive and represents the growth of the layer of reaction products accompanied by weight increase.

Another case is a homogeneously growing single-phase layer that allows slow transport of the corrosive medium to the corroded material by diffusion. Steady-state means that the thickness of the diffusion layer increases with time, while the absolute value of the concentration gradient remains constant. In this situation we also apply the first Fick's law, with the equation assuming a parabolic form, where k_p is the rate constant (Eq. 14):

$$(\Delta x)^2 = k_p t \quad (14)$$

Another case of passive corrosion is represented by the situation where the reaction products that form on the glass surface completely block the access of the corrosive agent, resulting in a rapid reduction in the surface area available for chemical reactions. The process is described by a logarithmic dependence (Eq. 15):

$$\Delta x = k_t t + k_{\log} \log t \quad (15)$$

with the logarithmic rate constant $k_{\log}$. If the corrosion is controlled by diffusion through the passivating layer and the crystallized phase completely blocks the corrosive agent or its diffusion coefficient is much smaller than that of the original layer, the effective cross-section for transporting the corrosive agent decreases rapidly.

However, in real life, the situation is more complex, and the dissolution rates of glass are influenced by numerous parameters (temperature, pH, the chemical composition of an aqueous system, and a solid phase), which are in most cases time-dependent. The concepts originally developed in geochemical literature were adopted to glass corrosion by a number of authors, e.g., Grambow (1985), Advocat *et al.* (1990), Bourcier *et al.* (1990), Grambow (1992), Helebrant (1997), and McGrail *et al.* (1997). In its most general form, the corrosion rate can be expressed by Eq. (16) (Conradt, 2008):

$$r = r_+ f(i) \left(1 - \frac{I_p}{I_{ps}} \right) \quad (16)$$

With the symbols denoting the following quantities: r - corrosion rate, r_+ - a forward rate, and $f(i)$ a term summarizing the effects of dissolved species i on the dissolution rate. The term $1 - I_p/I_{ps}$ expresses the degree of saturation of the solution in terms of the respective ion activity product I_{ps} with the index s denoting saturation. The forward rate r_+ is expressed as (Advocat *et al.*, 1990):

$$r_+ = X \cdot e^{\left(-\frac{E_A}{RT}\right)} e^{\left(-\frac{\Delta G_h}{RT}\right)} \quad (17)$$

where X is a constant, E_A the activation energy (for silicate glasses usually around 80 kJ/mol (Scholze, 1990)), and ΔG_h is the Gibbs energy of hydration.

Due to the lack of experimental data on the nature and time dependence of precipitated layer thickness, the mathematical description of its formation is mostly based on a semi-empirical approach. The precipitation can take place either by back precipitation of the species dissolved from glass (e.g., during the dissolution of glass in deionized water) or by precipitation of the species originally contained in the corrosion medium (e.g., during the dissolution of bioactive glasses in simulated body fluids). In both cases, two mechanisms of precipitated layer formation can be considered: (a) the activity products of dissolved ions exceed their solubility products, and new phases are formed by precipitation from the solution. The second mechanism assumes a direct reaction of ions in a sub-surface zone (Fig. 2) at the glass-liquid interface. For both mechanisms, the rate of precipitation is assumed to be directly proportional to the rate of dissolution (Conradt, 2008). The precipitation rate R_p can be expressed as a function of supersaturation with respect to precipitated compounds (Eq. (18), Mann *et al.*, 1989):

$$R_p = k_p \left[\left(\frac{I_p}{K_s} \right)^{\frac{1}{j}} - 1 \right]^n \quad (18)$$

Where i is the exponent reflecting the precipitation mechanism, K_s is the solubility product, and j the number of ions in the precipitated compound. The thickness h of the precipitated layer can be described by Eq. (19) (Helebrant, 1997):

$$h = h_n \left(1 - e^{-\frac{k_h}{t}} \right) \quad (19)$$

where h_n represents is the final layer thickness and k_h represents a rate constant.

Parameters Influencing the Corrosion of Glass

As mentioned above, corrosion of glass is a process influenced by many parameters, which are specific for any particular system glass-corrosion environment. For the sake of simplicity, in this section we will focus on the systems most relevant from a practical point of view, i.e., oxide (and in most cases silicate) glasses exposed to an aqueous environment. The parameters influencing the corrosion of glass can be attributed to the properties of corroded material (the composition and structure of glass, its surface finish), the characteristics of the corrosion medium (pH, ionic strength, presence of buffers), and the conditions of corrosion process (temperature, surface area to solution volume ratio, static versus dynamic conditions).

The dissolution rate and corrosion mechanisms of glasses critically depend also on the quality of the corroded surface and the formation and presence of corrosion and gel layers, and the layers of reaction products formed in the process of corrosion. Mechanical surface damage by e.g., grinding or polishing can become an initiation point of corrosion and its penetration into the depth of the material.

Characteristics of the Corrosion Medium

In general, the silicate glasses are most stable in slightly acidic, neutral, or slightly basic environment (pH ~ 4–8), less stable in strong acids, and poorly corrosion resistant in strongly basic solutions.

The ionic strength, i.e., the presence of dissolved ionic salts has a significant influence on the elementary mechanisms of corrosion. For example, a 1 M NaCl solution at the neutral pH accelerates the corrosion rate of silicate glasses in the same manner as a 1 M solution of HCl (Conradt, 2018). The presence of alkali ions in a solution significantly increases the number of surface charges in the weakly acidic or neutral solutions, thus enhancing the glass dissolution rate. This must be considered especially during *in vitro* tests of bioactive glasses, as the physiological fluids in the human body contain approximately 9 g L⁻¹ of NaCl.

Buffers in corrosion solutions not only maintain the pH at a constant level but also interfere with elemental mechanisms of glass dissolution. Moreover, the pH in a bulk of the corrosion medium might significantly differ from the pH at the liquid/glass interface since some products of glass dissolution, e.g., siliceous acid, also act as buffers.

Conditions of the Corrosion Process

Temperature is a parameter that critically influences the corrosion and dissolution of glass in aqueous media. The activation energy of dissolution of a silicate glass in aqueous media usually ranges between 60 and 80 kJ mol⁻¹, which means that the increase of temperature by 10K increases the reaction rate by a factor of 2.3 (Oelkers *et al.*, 2009). The change of temperature also affects thermochemical equilibria (solubilities), thus influencing the formation of layers of corrosion products.

In addition to temperature, corrosion/dissolution of glass is influenced also by the ratio of the surface of the material to the volume of the corrosive medium A/V . With other parameters constant, the A/V parameter significantly influences the rate of glass dissolution (Kamizono *et al.*, 1989; Fillet *et al.*, 1986). Under laboratory conditions, the A/V ratio for monolithic samples usually ranges from 0.001 cm⁻¹ to 100 cm⁻¹. When the area of the sample is large with respect to the volume of the corrosive medium

($A/V > 10 \text{ cm}^{-1}$), supersaturation of the corrosive solution by the components leached out of the materials can be achieved relatively quickly. This situation is common if the chemical/corrosion resistance of glass is tested under static conditions (i.e., without the exchange of the corrosive medium). This experimental arrangement is mainly used for the identification and analysis of the formed corrosion products and simulation of long-term action of the corrosion process. Due to the saturation effect, the surface of the monitored samples under static conditions is usually less degraded than in the samples tested at lower A/V values, or under a dynamic (flow-through) arrangement of the corrosion test.

Molecular Mechanism of Glass Corrosion in Aqueous Media

Depending on the conditions, water, even distilled water, becomes an aggressive corrosive agent. Due to the strong polarity of the O–H bonds and the bent shape, the water molecule has a strongly polar character: as the glass interacts with water, the solvent molecules cluster around ions on the glass surface so that the positive poles of dipoles seek proximity to anions and negative poles center over cations. The ions are electrostatically attracted outwards from the glass surface: as a result, the attractive forces between the ions are substantially weakened. More often, however, chemical bonds of the donor-acceptor type are formed between cations and water molecules during hydration, and complexes of metal ions with water molecules are formed (Gažo, 1981). Inter-molecular (i.e., adsorption) interactions are among the most common chemical reactions that occur when a glass surface comes into contact with water as a solvent. These include surface complexation reactions (e.g., hydrolysis) as well as electrical interactions on the surface.

When silica-based glasses are exposed to an aqueous environment, several processes are usually considered. An electrochemical equilibrium is established first, within a very short period of time at the order of magnitude of a few tens of milliseconds (Bauke, 1985).

Subsequently, sodium ions are mobilized by excess charge resulting from protons entering the electron cloud of oxygen atoms at the glass surface, forming $\equiv\text{Si-OH}$ groups immediately. The glass (silica) matrix is then dissolved: silicon atoms go through a transition, energetically unfavorable state, forming activated complexes. The nature of these states depends on the surface charge equilibrium, influenced by the pH (Oelkers *et al.*, 2009). The two different types of transient states in the basic and acidic environment are described by Eqs. 20 and 21, respectively:

In both cases siloxane bonds $\equiv\text{Si-O-Si}\equiv$ are split into two silanol groups $\equiv\text{Si-OH}$ (Eq. 22).

After splitting all siloxane bonds of a SiO_4 tetrahedron, silica dissolves as siliceous acid. The amount of silica released to the solution depends on the coverage of the glass surface by charges, which is strongly influenced by the pH of the system. Regardless of the dissolution mechanism, a new thermodynamic equilibrium is established within the solution.

Subsequently, dynamic back and forth recombination reactions increase the connectivity of the glass structure and generate interstitial water molecules (Oelkers *et al.*, 2009; Scholze, 1959). This process is strongly influenced by the presence of glass modifiers, especially Na. Some studies conclude that the reaction described by the Eq. (22) is more relevant for the generation of OH groups in the glass structure than the reaction between molecular water and siloxane bonds (Eq. (23)), Behrens and Stuke (2003):

If Na^+ is later leached from the glass structure, the remaining matrix cannot contain such high amounts of OH^- groups, and condensation of molecular water in the glass structure occurs (Smets and Lommen, 1981). The subsurface zone is thus converted to a gel, consisting of a percolating SiO_2 network and H_2O molecules (Conradt, 2008). An exchange of ions and water molecules then continues between the gel zone and the solution. Finally, the outermost layer condenses to a dense silica network. The structural compaction results from condensation of initially formed silanol groups yielding a network with enhanced connectivity (Casey *et al.*, 1993; Portal and Sempere, 2003), and rendering a water-exposed glass surface more corrosion resistant than the original surface of the as-produced glass.

As a result of the processes described above, a subsurface layer with a chemical composition different from that of the bulk glass (not to be mixed with the formation of a layer of reaction products precipitating at the surface of glass due to supersaturation of corrosion media) forms at the contact between the liquid and the glass surface (Fig. 2, Conradt, 2008). Starting from the solution/glass interface, the layer consists of a transition zone, a zone with approximately constant water content, and a transition zone to the bulk (Scholze, 1975). Well established local chemical equilibria are characteristic for the subsurface zone. The depletion of elements from the zone does not follow the categories of a network former versus a network modifier, but rather their elemental solubilities in water. In some cases, crystalline precipitates may form in the subsurface zone (Portal and Sempere, 2003).

Structure, Composition, and Corrosion of Glass

The rate of glass degradation is often related to the network connectivity of its structure. It has been — at least partially successfully — applied for predicting degradation rate and hence, the bioactivity of a range of bioactive glasses (Hill and Brauer, 2011). This approach, however, requires reliable information on glass structure expressed in terms of an average number of bridging oxygens in the glass structure. This can be relatively reliably assessed for silicate glasses but runs into problems if additional network formers, e.g., phosphorus or boron with complex structural functions are present.

An alternative thermodynamical approach based on the works of Paul (1982) and Grambow (1992) has been therefore proposed. The approach is based on three assumptions: (1) the forward rate of the rate-controlling elementary step is temperature and pH-dependent; (2) the reaction turnover dependent Gibbs energy of hydration of glass, ΔG_{hydr} , accounts for glass composition effects; (3) the solubility product of the rate-controlling species (for silicate glasses usually SiO_2) is considered (Conradt, 2001). However, the solubility of amorphous silica is significantly influenced by the aqueous environment. Moreover, the traditional thermodynamic approach, which considers the ΔG_{hydr} as a parameter accounting for glass degradation, does not account for the effect of glass composition in an appropriate way. The ΔG_{hydr} is often calculated from the weighted contributions of hydration reactions of individual species, assuming that glass is a physical mixture of oxides and metasilicates, and to a great extent ignoring the glass structure as we understand it today (Conradt, 2001). The main problem is related to the fact, that with this attitude a glass must be considered an extremely non-ideal mixture of its oxide components, and requires consideration of mixing, structural and configurational effects. These difficulties can be overcome by the constitutional approach, based on the work of e.g., Shakhmatkin *et al.* (1994), who described glass as a mixture of its constitutional phases. In this case, the main constitutional problem is the determination of the crystalline reference state (C_R) of the glass. For a simple system, this information is contained directly in the respective phase diagram. For a more complex, multi-component, system a predominant ternary or quaternary oxide system is determined first. The constitutional phases from this system are then considered as major mineral phases in the system. The molar amounts of the phases are calculated from the composition of glass, and the thermodynamic quantities are determined. It has been confirmed that this approach correctly accounts for glass composition and yields significantly improved values of ΔG_{hydr} as a major parameter influencing the hydrolytic resistance of glass. However, many glasses exhibit a strong pH dependence of their degradation behavior, which cannot be explained merely on the basis of the ΔG_{hydr} values. These findings are usually interpreted through the coverage of glass surface by charged groups, expressed in terms of a surface coverage factor θ :

$$\theta \approx \sum_j \frac{k_j c_j}{1 + k_j c_j} \quad (24)$$

with k_j representing the adsorption of the charged species j , where $j = \text{H}^+, \text{OH}^-, \text{R}^+, \dots$, and c_j standing for its concentration. The pH dependence of the rates of degradation of glass is then determined by both ΔG_{hydr} and $\log \theta$.

Conclusions

Corrosion and chemical degradation of glass are the processes, which markedly deteriorate the properties of glass products and limit their use. Due to a broad variety of glass compositions, and variability of corrosion environments, there exists no unified methodology of evaluation of glass corrosion properties, nor is there a possibility to describe the degradation of all types of glasses by a well defined and generally valid model with reliable predictive capacity. A constitutional approach describing glass as a mixture of its mineral constituents was found to provide a reliable estimation of degradation properties of several industrially relevant silicate glasses. Irrespective of the approach applied, any glass corrosion model relies on an adequate description of the adsorption equilibria established at the surface of glass exposed to an aqueous environment, correct determination of the Gibbs energy of formation of glass from elements and the Gibbs energy of formation of the aqueous system. The coverage of glass surface exposed to aqueous media by charged species, including H^+ and OH^- , is a key parameter for pH dependence of the rate of degradation.

VOLUME 1

Overview: Manufacture of Ceramics and Microstructural Developments in Ceramics <i>Francis Cambier and Anne Leriche</i>	1
Synthesis of Oxide and Non-Oxide Advanced Ceramics <i>Prashant N Kumta</i>	2
Synthesis of Ceramic Powders by Wet Chemical Routes <i>Paola Palmero</i>	27
Self-Propagating High-Temperature Synthesis <i>Jerzy Lis</i>	40
Hydrothermal Synthesis <i>Ender Suvaci and Emel Özel</i>	59
Ultrasonic Sprayed Aerosol for Ultrafine Ceramic Powder Synthesis <i>Sylvie Foucaud and Yann Leconte</i>	69
Calcination and Phase Transformations <i>Gary L Messing</i>	83
Preceramic Polymers as Precursors of Advanced Ceramics: The Polymer-Derived Ceramics (PDCs) Route <i>Yuji Iwamoto, Günter Motz, Emanuel Ionescu, and Samuel Bernard</i>	93
Organic Additives in Ceramic Processing <i>Anne Aimable and Thierry Chartier</i>	103
Powder Mixing and Grinding Processes for Ceramics <i>David Houivet and Jérôme Bernard</i>	112
Powder Granulation and Compaction <i>Michele Dondi</i>	136
Colloid Casting Processes: Slip Casting, Centrifugal Casting, and Gel Casting <i>Nur S Yüzbaşı and Thomas Graule</i>	146
Processing of Ceramics by Direct Coagulation Casting <i>Margarida Almeida and Joaquim M Vieira</i>	154
Extrusion <i>Stuart Blackburn and Marcin Szymiczek</i>	162
Ceramic Injection Molding <i>Moritz v Witzleben and Tassilo Moritz</i>	179

Tape Casting and Lamination <i>Eric R Twiname</i>	189
Freeze Casting <i>Dominique Hautcoeur</i>	195
Additive Manufacturing <i>Andrea Zocca, Giorgia Franchin, Paolo Colombo, and Jens Günster</i>	203
Green Machining of Ceramics <i>Fabrice Petit</i>	222
Screen Printing <i>Danjela Kuscser</i>	227
Sintering of Ceramics: An Overview <i>Anne Leriche, Francis Cambier, and Stuart Hampshire</i>	233
Solid-State Sintering <i>John E Blendell and Wolfgang Rheinheimer</i>	249
Liquid Phase Sintering: Fundamentals <i>Suk-Joong L Kang</i>	258
Viscous Sintering <i>George W Scherer</i>	265
Hot Pressing and Hot Isostatic Pressing <i>Mathias Herrmann and Jan Räthel</i>	270
Reaction Sintering <i>Carmen Baudín</i>	278
Flash Sintering and Other Rapid Sintering Techniques <i>David Salamon</i>	286
Spark Plasma Sintering <i>Umberto Anselmi-Tamburini</i>	294
Cold Sintering and Hydrothermal Sintering <i>Graziella Goglio, Arnaud Ndayishimiye, Catherine Elissalde, and Clive A Randall</i>	311
Microwave Sintering of Ceramics <i>Jean-Marc Chaix</i>	327
Porous Ceramics Processing <i>Manabu Fukushima, Akihiro Shimamura, Paolo Colombo, Hideki Hyuga, Tatsuki Ohji, and Yu-ichi Yoshizawa</i>	342
Porous Ceramics Including Fibrous Insulation, Structure and Properties of <i>M Fukushima, T Ohji, P Colombo, and Y-I Yoshizawa</i>	346
Control of the Microstructure in Ceramics <i>Anne Leriche, Stuart Hampshire, and Francis Cambier</i>	349
Templated Grain Growth of Textured Ceramics <i>Gary L Messing</i>	367
Functionally Graded Ceramics <i>Omer Van der Biest and Achim Neubrand</i>	374
Transparent Ceramics: Materials, Processing, Properties and Applications <i>Marc Rubat du Merac</i>	399
Geopolymers and Geopolymer-Derived Composites <i>Waltraud M Kriven</i>	424

Overview: Characterization and Modelling of Ceramics and Glasses <i>Michael Pomeroy and Stuart Hampshire</i>	439
Ceramic Genomics: Total Bond Order Density <i>Wai-Yim Ching</i>	441
Predictive Modeling of Ceramic Materials <i>Sarah Guerin, Syed AM Tofail, and Damien Thompson</i>	475
Molecular Dynamics Simulations of Glass Structure <i>Mattias Edén</i>	481
Computation of Phase Diagrams for Ceramics <i>Sara Serena, Angel Caballero, Antonio H de Aza, and Maria A Sainz</i>	498
Characterization of Ceramic Powders <i>Martin J Murtagh and Navin Venugopal</i>	517
Amorphous Materials: Vibrational Spectroscopy <i>PF McMillan</i>	530
MAS NMR Analysis of Ceramics and Glasses <i>Yajie Gao</i>	536
X-Ray Powder Diffraction <i>Scott T Mixture</i>	549
Case Studies in the X-ray Diffraction of Ceramics <i>Maurice Gonon</i>	560
Introduction to Transmission Electron Microscopy; The Basics <i>Ann-Katrin Fetzer, Maximilian Trapp, Stefan Lauterbach, and Hans-Joachim Kleebe</i>	578
High Resolution Analytical Electron Microscopy of Ceramics and Glasses <i>Jennifer Cookman, Michele Conroy, and Ursel Bangert</i>	600
Introduction to Three Dimensional Electron Crystallography <i>Andrew Stewart and Ute Kolb</i>	618
Preparation of Ceramic, Glass-Ceramic and Glasses for Microstructural Examination <i>Michael J Pomeroy</i>	634
Scanning Electron Microscopy for Ceramics and Glasses <i>Michael J Pomeroy</i>	651
Fractography: Brittle Materials <i>John J Mecholsky, Jr.</i>	662
Thermal Analysis Techniques for Technical Ceramics and Glasses <i>Michael J Pomeroy</i>	676
High-Temperature Characterization of Glasses and Melts <i>Sohei Sukenaga and Hiroyuki Shibata</i>	689
Overview: Mechanical and Physical Properties and Property Testing of Ceramics and Glasses <i>Anne Leriche and Francis Cambier</i>	704
Elastic and Inelastic Behavior of Ceramics <i>Daniele Mari and Robert Schaller</i>	705
Indentation of Ceramics <i>Emilio Jiménez-Piqué</i>	718
Contact Damage Resistance and Tribological Behavior of Ceramic/Carbon Nanostructure Composites <i>Manuel Belmonte</i>	733

Methods of Determination of Young's Modulus and Tensile, Flexural and Compressive Strength <i>Sylvain Meille</i>	745
Fracture Toughness Measurement <i>Tanja Lube</i>	762
R-Curve Behavior of Ceramics <i>Marc J Anglada</i>	775
Subcritical Crack Growth: Basic Relations and Experimental Evaluation <i>Malika Saâdaoui</i>	797
Subcritical Crack Growth: Modeling of the v-K Curve in Different Environments <i>Raul Bermejo</i>	811
Ceramics: Transformation Toughening <i>DB Marshall and RHJ Hannink</i>	818
Mixed-Mode Fracture and Microstructural Aspects of Crack Propagation <i>Delia Gutiérrez-Campos and Yuk Ming X Hung-Hung</i>	823
R-Ratio and Microstructure Effects <i>Delia Gutiérrez-Campos, Eliana Pinto-González, and Elvira Saab-Llatas</i>	841
Thermal Properties of Ceramic Materials <i>David S Smith and Benoît Naït-Ali</i>	855
Thermal Shock Behavior of Ceramics: Fundamentals and Thermal Shock Resistance Parameters <i>Carmen Baudín</i>	867
Thermal Shock and Thermal Fatigue Behavior of Ceramics: Microstructural Effects <i>Gilbert Fantozzi and Malika Saâdaoui</i>	879
Creep Behavior of Ceramics <i>Gilbert Fantozzi and Arturo Dominguez-Rodriguez</i>	891
Nonoxide Ceramics, Creep and Creep Rupture of: Silicon Nitrides and Silicon Carbides <i>SM Wiederhorn</i>	908
Dislocations in Ceramic Materials <i>Jacques Rabier</i>	911
Corrosion of Ceramics in Aqueous Environments <i>Mathias Herrmann</i>	921
Corrosion and Degradation of Glass <i>Dagmar Galusková and Dušan Galusek</i>	932

VOLUME 2

Overview: Oxide Ceramics and Non-oxide Ceramics <i>Stuart Hampshire and Michael Pomeroy</i>	1
Structural and Thermostructural Ceramics <i>Jon Binner and Tammana SRC Murthy</i>	3
Alumina, Structure and Properties <i>Carmen Baudín</i>	25
Low Thermal Expansion Ceramic and Glass-Ceramic Materials <i>Pascal Pilate and Florimond Delobel</i>	47

Mullite: Structure and Properties <i>Gi��le L Lecomte-Nana and Aghiles Hammas</i>	59
Aluminum Titanate, Structure and Properties <i>Salvador Bueno and Carmen Baud��n</i>	76
Zirconia Ceramics, Structure and Properties <i>Anne Leriche, Francis Cambier, and Helen Reveron</i>	93
Si ₃ N ₄ -Ceramics: An Introduction <i>MJ Hoffmann</i>	105
Si ₃ N ₄ Ceramics, Structure and Properties <i>Monika Tatarkov��, Peter Tatarko, and Pavol ��ajgal��k</i>	109
SiALONs and the Representation of Phase Relationships <i>Stuart Hampshire</i>	119
Si-Al-O-N Ceramics, Structure and Properties <i>Ali ��elik and Servet Turan</i>	128
Aluminum Nitride and ALON Ceramics, Structure and Properties of <i>JW McCauley</i>	144
SiC Ceramics, Structure, Processing and Properties <i>Young-Wook Kim and Rohit Malik</i>	150
High Thermal Conductivity Ceramics <i>Mikito Kitayama</i>	165
MAX Phases, Structure, Processing, and Properties <i>Nick Goossens, Bensu Tunca, Thomas Lapauw, Konstantina Lambrinou, and Jozef Vleugels</i>	182
ZrB ₂ , HfB ₂ , OsB ₂ and IrB ₂ Boride Ceramics: Processing, Structure, and Properties <i>Nina Orlovskaya, Holden Hyer, Yongho Sohn, Mykola Lugovy, Gurdial Blugan, Thomas Graule, Jakob Kuebler, Sergey Yarmolenko, Jagannathan Sankar, and Michael J Reece</i>	200
Directionally-Solidified Eutectic Oxide Ceramics <i>VM Orera^{��} and J Llorca</i>	216
Overview: High-Performance Ceramics and Ceramic Composites <i>Michael Pomeroy</i>	225
Ceramic Matrix Composites With Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior <i>Gilbert Fantozzi and J��r��me Chevalier</i>	227
Nanoscale Ceramic Composites <i>GS Thompson and MP Harmer</i>	240
Ceramic Matrix Graphene and Carbon Nanotube Composites <i>Katalin Bal��zsi, M��nika Furk��, and Csaba Bal��zsi</i>	243
Short Fiber Ceramic Matrix Composites (SF-CMCs) <i>Walter Krenkel, Stefan Flauder, and Georg Puchas</i>	260
Glass and Glass-Ceramic Matrix Composites for Advanced Applications: Part I: Properties and Manufacturing Technologies <i>Dino Boccaccini, Maria Cannio, Enrico Bernardo, and Aldo R Boccaccini</i>	277
Glass and Glass-Ceramic Matrix Composites for Advanced Applications: Part II: Applications <i>Dino Boccaccini, Maria Cannio, Enrico Bernardo, and Aldo R Boccaccini</i>	288

^{  }Deceased.

High Performance Fibers <i>AR Bunsell</i>	304
Spun (Slurry and Sol–Gel) Ceramic Fibers <i>DM Wilson</i>	314
Ceramic Matrix Fiber Composites <i>Francis Rebillat</i>	317
Ultra-High Temperature Ceramic Matrix Composites <i>Luca Zoli, Diletta Sciti, Antonio Vinci, Pietro Galizia, Frédéric Monteverde, Simone Failla, and Laura Silvestroni</i>	340
Carbon-Matrix Composites <i>Deborah DL Chung</i>	353
Ceramics in Space Applications <i>Barry Twomey, Daithi de Faoite, Kevin AJ Doherty, and Kenneth T Stanton</i>	359
Porous Ceramics for Energy Applications <i>Andreas Kaiser, Bhaskar R Sudireddy, and Farid Akhtar</i>	380
Joining of Advanced Ceramics <i>John A Fernie and Kevin M Knowles</i>	393
Abrasives <i>Jean-André Alary</i>	406
Wear and Erosion Resistant Ceramic Materials <i>Pavol Hvizdoš</i>	416
Wear and Erosion Resistant Ceramic Coatings <i>František Lofaj and Marián Mikula</i>	425
Oxidation and Corrosion of Non-oxide Ceramics <i>NS Jacobson and EJ Opila</i>	440
Overview: Glass and Glass Ceramics <i>Stuart Hampshire</i>	445
The Glassy State <i>Maziar Montazerian and Edgar D Zanutto</i>	448
Glasses: Alkali and Alkaline-Earth Silicates <i>Benjamin JA Moulton and Grant S Henderson</i>	462
Soda-Lime-Silica Glasses <i>Russell J Hand</i>	483
Glasses: Aluminosilicates <i>Laurent Cormier</i>	496
Borosilicate Glasses <i>Yuanzheng Yue, Manzila I Tuheen, and Jincheng Du</i>	519
Glasses: Chalcogenides <i>Myungkoo Kang and Kathleen A Richardson</i>	540
Glasses: Oxynitride Glass Formation and Structure <i>Stuart Hampshire</i>	555
Glasses: Oxynitride Glass Properties and Crystallization <i>Stuart Hampshire</i>	569
Glasses: Phosphates <i>Andrea Moguš-Milanković, Ana Šantić, and Luka Pavić</i>	580

Halide Glasses <i>Marcel Poulain</i>	591
Glass: Annealing and Tempering <i>Mathieu Hubert and Peter J Lezzi</i>	623
Glass: Chemical and Thermal Strengthening <i>Ali Talimian and Vincenzo M Sglavo</i>	632
Properties of Glass Materials <i>M Hasanuzzaman, A Rafferty, M Sajjia, and A-G Olabi</i>	647
Optical Glass: Challenges From Optical Design <i>Ulrich Fotheringham, Martin Letz, Uwe Petzold, Simone Ritter, and Yvonne Menke-Berg</i>	658
Glass Fibers <i>KK Chawla</i>	676
Glass: Optical Fibers – Manufacture and Properties <i>Conleth D Hussey</i>	681
Glasses: Sol–Gel Methods: An Introduction <i>T Woignier and J Phalippou</i>	689
Glasses and Glass-Ceramics Prepared by Sol–Gel <i>María E Cruz, Yolanda Castro, and Alicia Durán</i>	695
Glass-Ceramics and Their Applications <i>Maurice Gonon and Florian Dupla</i>	709
Glass Reactive Sintering <i>Acacio Rincon Romero, Hamada Elsayed, Jozef Kraxner, and Enrico Bernardo</i>	728
Glasses and Glass-Ceramics as Sealing Materials <i>María J Pascual</i>	746
Glasses and Glass-Ceramics for Nuclear Waste Immobilization <i>Daniel Caurant and Odile Majérus</i>	762

VOLUME 3

Overview: Electroceramics and Ceramics and Glasses in Energy Generation and Storage <i>Carmen Galassi</i>	1
Photovoltaics: Advanced Inorganic Materials <i>Abdelilah Slaoui and Reuben T Collins</i>	5
Ion Conducting Materials: Superionic Conductors and Solid-State Ionics <i>Junichi Kawamura</i>	17
Development, Structure, and Mechanical Properties of Sulfide Solid Electrolytes <i>Koji Ohara, Atsushi Sakuda, and Akitoshi Hayashi</i>	38
Solid Oxide Fuel Cells <i>Alessandra Sanson and Angela Gondolini</i>	49
Laser Processing of Energy Storage Materials <i>Heungsoo Kim and Alberto Piqué</i>	59
Aluminum, Gallium, and Indium Nitrides <i>Qilin Hua, Bei Ma, and Weiguo Hu</i>	74
Novel Nitride Phosphors <i>M Bettinelli</i>	84

Phosphors: VUV Excitation <i>Jean-Claude Krupa and AZMS Rahman</i>	89
Silicon Carbide Electronic Devices <i>PG Neudeck and GK Sujan</i>	93
Scintillator Crystals <i>D Klimm</i>	103
Ceramics for Laser Technologies <i>Jan Hostaša</i>	110
Ceramic Sensors for Industrial Applications <i>David Degler, Frank Allmendinger, and Nicolae Barsan</i>	125
Pyroelectric Crystals, Ceramics, and Thin Films for IR Sensors <i>Roger W Whatmore</i>	139
Superconducting Materials <i>Peter Majewski</i>	151
Superconductors: Borocarbides <i>Günter Fuchs, Karl-Hartmut Müller, and Vladimir N Narozhnyi</i>	162
The RABiTS Approach for Second Generation (2G) High Temperature Superconductors <i>Martin W Rupich</i>	174
Ferrite Ceramics at Microwave Frequencies: Applications and Characterization <i>Jean-Luc Mattei, Alexis Chevalier, and Vincent Laur</i>	183
Ferrite Magnets: Properties and Applications <i>Jean-Marie Le Breton</i>	206
Ferrites <i>PJ van der Zaag</i>	217
Multiferroic Composites <i>Xianfeng Liang, Huaihao Chen, Cheng Tu, Zhaoqiang Chu, Cunzheng Dong, Yifan He, Yuyi Wei, Yuan Gao, Hwaider Lin, and Nian X Sun</i>	225
Zinc-Oxide-Based Electronics and Photonics <i>David J Rogers, Ferechteh H Teherani, Eric V Sandana, and Philippe Bove</i>	241
Varistor Electrical Properties: Microstructural Effects <i>Zumret Topcagic and Thomas E Tsovilis</i>	254
Latest Trend of ZnO Multilayer Ceramic Varistors <i>Eiichi Koga, Yoshiko Higashi, and Michio Matsuoka</i>	272
Dielectric, Ferroelectric, Antiferroelectric, Relaxor, Piezoelectric Ceramics: Definitions and Main Applications <i>Floriana Craciun</i>	281
Electroceramics: Modeling of Sintering, Microstructure Evolution and Functional Properties <i>Constantin Hutanu, Vlad Alexandru Lukacs, and Liliana Mitoseriu</i>	295
BaTiO ₃ -Based Ceramics: Fundamentals, Properties and Applications <i>Vincenzo Buscaglia, Maria Teresa Buscaglia, and Giovanna Canu</i>	311
The PZT System <i>Florian Jean and Christian Courtois</i>	345
Lead-Free Piezoelectric Ceramics <i>Barbara Malič, Mojca Otoničar, Kristian Radan, and Jurij Koruza</i>	358

Electrostrictive Ceramics and Their Applications <i>Simone Santucci and Vincenzo Esposito</i>	369
Low-Loss Ceramics in Mobile Communications <i>K Wakino, H Tamura, and GK Sujan</i>	375
Small-Scale Energy Harvesting Devices for Smart Electronics <i>Sumanta Kumar Karan, Rammohan Sriramdas, Min-Gyu Kang, Yongke Yan, and Shashank Priya</i>	391
Multilayer Ceramic Actuators <i>K Uchino</i>	426
Multilayer Glass–Ceramic/Ceramic Composite Substrates <i>Jobin Varghese, Nina Joseph, and Heli Jantunen</i>	437
Functional Ceramics through Novel Chemical Approaches <i>K Kato, Y Torii, and G Majumdar</i>	452
Overview: Bioceramics and Bioreactive Glasses <i>Anne Leriche and Francis Cambier</i>	458
Bone as a Material: Lessons From Nature <i>Laura M O'Sullivan and Laoise M McNamara</i>	459
Overview of Substitutes for Bone Replacement: Natural and Synthetic Products <i>Nicolas Somers and Marie Lasgorceix</i>	473
New Trends in Ceramics for Orthopedics <i>Laurent Gremillard and Jérôme Chevalier</i>	493
New Trends in Ceramics for Dentistry <i>Paola Palmero</i>	501
Oxide Ceramics for Biomedical Applications <i>Corrado Piconi and Anna Tampieri</i>	511
Non-Oxide Ceramics as Biomaterials <i>Stuart Hampshire</i>	526
Carbon in Biomedical Engineering <i>Jill S Kawalec</i>	533
Yttria-Stabilized Zirconia as a Biomaterial: From Orthopedic Towards Dental Applications <i>Helen Reveron and Jérôme Chevalier</i>	540
ZTA Ceramics for Biomedical Applications <i>Frank Kern, Paola Palmero, and Wolfgang Burger</i>	553
Phosphates <i>David Grossin</i>	567
Apatitic and Tricalcic Calcium Phosphate-Based Bioceramics: Overview and Perspectives <i>Christophe Drouet and Christèle Combes</i>	575
Calcium Phosphates in Biomedical Engineering <i>Maria Canillas, Antonio H de Aza, and Miguel A Rodríguez</i>	595
Bioceramics in Regenerative Medicine <i>Simone Sprio, Anna Tampieri, Massimiliano Dapporto, Michele Iafisco, and Monica Montesi</i>	601
Bioactive Glasses and Glass-Ceramics <i>Francesco Baino</i>	614
Calcium Phosphate Cements <i>Aoife Culliton and Eamonn De Barra</i>	624

Bone Regeneration With Ceramics Scaffold <i>Vida Strasser and Maja Dutour Sikirić</i>	646
Advanced Processes for the Design of Customized Ceramic Medical Devices <i>Eric Champion and Patricia Pascaud-Mathieu</i>	662
Bioactive and Biodegradable Polymer-Based Composites <i>Lukas Gritsch and Aldo R Boccaccini</i>	674
Surface Treatment of Bioceramics <i>Nicolas Somers and Marie Lasgorceix</i>	701
Chemical Functionalization of Calcium Phosphate Bioceramic Surfaces <i>Chantal Damia, Amandine Magnaudeix, and Betty Laverdet</i>	716
Thermally Sprayed Materials for Biomedical Applications <i>Andreas Killinger and Rainer Gadow</i>	732
Design of Tissue Engineering Scaffold by Means of Mathematical Modeling <i>Stefan Scheiner</i>	750
Unconventional, Nature-Inspired Approaches to Develop Bioceramics for Regenerative Medicine <i>Anna Tampieri, Simone Sprio, Monica Sandri, Elisabetta Campodoni, Andrea Ruffini, Laura Mengozzi, and Silvia Panseri</i>	758
Assessment of Mechanical Properties of Bioceramics <i>Gilbert Fantozzi</i>	772
Mechanical Properties of Dental Ceramics <i>Fei Zhang and Jozef Vleugels</i>	784
Biological Assessment of Bioceramics: In Vitro and In Vivo Tests <i>Maria H Fernandes and Pedro de Sousa Gomes</i>	798
Zirconia Ceramics: Clinical and Biological Aspects in Dentistry <i>Andraž Kocjan, Tadej Mirt, Ralf-Joachim Kohal, Zhijian Shen, and Peter Jevnikar</i>	817
Subject Index	832

Overview: Oxide Ceramics and Non-oxide Ceramics

Stuart Hampshire and Michael Pomeroy, Bernal Institute, University of Limerick, Limerick, Ireland

© 2021 Elsevier Inc. All rights reserved.

Structural ceramics have been under development for many decades and many are now used in a wide range of advanced technological applications where high wear resistance and/or high temperatures combined with chemical stability are required. So as a result of these developments there is a range of ceramic materials available which are classified according to their chemistry: oxides, carbides, nitrides and borides, which are reviewed in the various chapters which follow.

The first chapter gives a complete overview of these structural and thermostructural ceramics, introducing the different groups above and their performance in major applications which enhance component life, increase efficiency of existing processes, reduce energy consumption or improve environmental impact. The different synthesis methods for these ceramics are introduced and their consolidation by different sintering techniques and how these lead to microstructural development that enhances their particular special properties.

The next chapter deals with Alumina ceramics which have the largest share of the world ceramics market. The crystalline structure and properties of single-crystal α -Al₂O₃ are described followed by the fabrication processes for alumina materials. Raw materials are available at relatively low cost and alumina components with wide ranges of shapes and sizes and controlled microstructure can be fabricated by pressureless sintering. A review of properties follows including hardness and stiffness, wear resistance, chemical inertness and associated corrosion resistance and strength, all of which can be retained at high temperature. They are excellent electrical insulators and can be made translucent or even transparent depending on grain size. Chemical inertness allows alumina to be used in biological environments. The main applications are described on the basis of the required properties.

The next chapter introduces ceramics and glass-ceramics which have low thermal expansion, materials which are of interest for applications which need dimension stability during temperature variation or special thermomechanical behavior such as a high thermal shock resistance. Some theoretical considerations are presented which explain the origin of low thermal expansion and its importance. An overview is given of ceramic and glass-ceramics which are well known for their low thermal expansion, such as silica, cordierite, aluminum titanate, zirconyl phosphate and NZP, and various glass-ceramics. Their main characteristics, fabrication processes and current or potential applications are outlined.

The wide technological applicability of mullite ceramics is reviewed in the next chapter. An overview of mullites is given, outlining mineralogy and crystal structure, their stability and composition, the main processing routes to form ceramics and the relevant typical final properties such as high thermal stability, low thermal expansion and conductivity, together with suitable strength and fracture toughness which, combined, give mullite its excellent thermal shock resistance. Finally applications in both traditional and advanced ceramics are described.

The main special characteristic of aluminum titanate (AT), a very low overall thermal expansion coefficient, is outlined in the next chapter. The strong anisotropy in the thermal expansion of its crystallographic directions is explained, as well as the causes of microcracking observed in AT. These features promote excellent thermal shock resistance but at the expense of strength. The structure, properties and applications of AT are summarized, together with a review of processing routes and technological applications. The inclusion of AT in the design of ceramic composite materials for structural applications is discussed whereby different toughening mechanisms operate in both monolithic and laminated alumina-based structures with different AT contents.

The next chapter reviews the crystallographic, physical and chemical properties of zirconia. Developed since the 1980s following the discovery of stabilization at room temperature of its high temperature phases, zirconia has continued to fascinate scientists and technologists by its particular characteristics of its solid solutions with other oxides leading to occurrence of mechanical toughening behavior (through manipulation of the tetragonal-monoclinic phase transformation) and special ionic conduction processes (in its cubic form). An outline is given of how the microstructure can be engineered such that very high fracture strength or high toughness can be generated. A section is given on wear, cutting, thermal barrier coatings, ionically conductive and biomedical applications.

The next two chapters are concerned with silicon nitride ceramics, the first providing an introduction to this major non-oxide ceramic. An overview is given of crystal structures and processing, whereby most silicon nitride ceramics are prepared by using α -rich Si₃N₄ powders with oxide additives which allow liquid formation and the transformation during sintering from α - to β -Si₃N₄. The microstructural development of growth of elongated β grains with high aspect ratios is described along with the characteristics of the intergranular films formed from the liquid phase which depend on additive chemistry. The microstructure-property relationships are discussed. The second contribution expands on this, showing that the properties are not only pre-determined by the intrinsic properties of Si₃N₄ single crystals, but also strongly depend on the size, orientation and volume fraction of the Si₃N₄ grains, as well as the chemistry and volume fraction of grain boundary phases. This means that properties of Si₃N₄ ceramics such as superior fracture toughness and high thermal conductivity can be significantly improved by tailoring the microstructure such that it can be used in automotive engine parts, heat exchangers, pump seals, ball bearings, cutting tools and ceramic armor as well as potential use in electronic and biomedical applications.

Related to silicon nitride are SiAlON ceramics which are solid solutions whereby Al and O substitute for Si and N in the α - and β - Si_3N_4 crystal structures and extra cations can be accommodated in the α -phase. An introduction to α - and β -SiAlONs and the representation of the Si-Al-O-N and related M-Si-Al-O-N systems, including the Jänecke prism, is given in the next chapter. The accompanying chapter explains how easier densification provided by oxide additives results in alpha/beta-SiAlON composites with lower glass content grain boundaries and better high temperature properties. An overview of the properties of SiAlON ceramics is given and how they are controlled by parameters such as phase ratio, solubility of Al and O ions in the Si_3N_4 structures, type of rare-earth additive used and crystallization of grain boundary phase(s). A brief section on applications is included describing structure-property-performance relationships in SiAlON ceramics.

Related to the SiAlONs is ALON, which can be thought of as a nitrogen-stabilized cubic aluminum oxide, and this is the subject of the next chapter which details both AlN and ALON, their crystal chemistry and the phase equilibria for the pseudo-binary Al_2O_3 -AlN system. Processing of AlN and ALON are described; small amounts of additives (rare earth oxides) are typically utilized to achieve fully dense, pore-free material and examples of microstructural development are presented. Properties are outlined, especially the high thermal conductivity for AlN. Carbothermal reduction enhances sintering of ALON and yields a transparent ceramic which makes it suitable for use in impact resistant windows or as an upconversion material (if Er and Yb oxides are used as sintering aids).

The next chapter reviews the scientific research and technological advances in SiC ceramics and discusses their current status in terms of the structure, processing methods, properties, and applications. The different crystal structures (polytypes) found for SiC are outlined. An overview follows of various processing techniques for SiC including pressureless sintering, gas pressure sintering (GPS), hot pressing, spark plasma sintering (SPS), reaction bonding (RBSC), recrystallization, chemical vapor deposition (CVD), and hot isostatic pressing (HIP). Examples of different microstructures are presented. Further discussion deals with the capability of different processing techniques to achieve high fracture energy, reduced flaw size, fine grain microstructure, and high density, which are prerequisites for achieving excellent mechanical properties. This includes details on their microstructure, porosity, and grain boundary chemistry, which in turn depend on the starting composition and processing technique. Finally, many of the most important structural and functional applications of SiC are outlined.

Because of emphasis in modern society on energy and environment-related issues, the latest power electronic devices need ceramic substrates with high thermal conductivity. In the next chapter, the developments of representative high thermal conductivity ceramics, silicon carbide, aluminum nitride and silicon nitride, are reviewed. In each case, intrinsic thermal conductivity is described followed by the basic ceramic processing techniques used and a discussion of the fundamental understanding of factors influencing and enhancing thermal conductivity, such as sintering additives and microstructural development.

The next chapter provides an introduction to MAX phases, or $\text{M}_{n+1}\text{A}_n\text{X}_n$ phases, which are a family of compounds within the class of complex or double carbides or nitrides where "M" refers to an early transition metal, "A" to an A-group element, "X" can be C and/or N and "n" is an integer (commonly 1, 2 or 3). It focuses on their multi-element nano-layered structure with atomic planes of A-atoms interleaving rock salt-structured $[\text{M}_6\text{C}]$ -octahedra, which form the basis for their unique set of both ceramic- and metal-like properties. Following an in-depth presentation on crystal structures, topics covered include processing of powders, thin film and bulk material synthesis, and an outline of their attractive properties.

The penultimate chapter in this section reviews Structure, Processing and Properties of Boride Ceramics: ZrB_2 , HfB_2 , OsB_2 and IrB_2 . Selected studies are described on synthesis of ReB_2 type hexagonal OsB_2 and IrB_2 powders by mechanochemistry of their precursor elements and their crystal structures are compared with commercial ZrB_2 and HfB_2 powders. All the borides have been densified using Spark Plasma Sintering (SPS) and densification, phase composition, microstructure analysis along with mechanical properties by nanoindentation of these diborides are presented.

The final chapter reviews Directionally Solidified Eutectic (DSE) Oxide Ceramics which consist of cubic zirconia, perovskite, or garnet phases of micron or nanometer size, dispersed in a continuous sapphire single crystalline phase grown from the melt. The combination of the outstanding creep behavior of Al_2O_3 along its c-axis with a huge amount of clean and strong grain boundaries, characteristic of the eutectic solids, results in a new set of ceramic oxides with excellent creep behavior and good mechanical properties up to 1700°C , even in corrosive environments. DSE ceramic oxides are thus envisaged as ultra-high temperature functional and structural materials.

In summary, the common theme throughout all of these chapters above is the composition-structure/microstructure-properties relationships.

Structural and Thermostructural Ceramics

Jon Binner, University of Birmingham, Birmingham, United Kingdom

Tammana SRC Murthy, University of Birmingham, Birmingham, United Kingdom and Bhabha Atomic Research Centre, Mumbai, India

Introduction

It is generally recognized that the progress of human civilization is intimately connected with the availability and development of two major resources – materials and energy. What is perhaps less appreciated is the inextricable relation between materials development and energy generation (Murthy, 2004). This interdependence has been continuously growing and it is engineering materials that hold the key to the large-scale production of energy from renewable energy sources, which reduces the CO₂ footprint. Besides safe operations, high efficiency energy production and transport are key areas of research in the world today (Binner *et al.*, 2020; Murthy, 2012). These can be realised by future technologies such as wind and wave power, second generation concentrated solar power generation, generation IV nuclear fission and fusion reactors, as well as for other applications ranging from aerospace through to hypersonic and re-entry space vehicles. Many of these technologies are conceptually ready to be demonstrated but are not currently capable of being realised at the industrial scale due to limitations in obtaining appropriate materials (Krenkel *et al.*, 2006). Amongst the engineering structural materials, advanced ceramics, including the oxides, borides, carbides, nitrides and silicides, have received widespread attention over the past few decades and are suitable for many engineering applications.

Ceramics can be classified very broadly into structural, functional and bio-ceramics based on the type of application; however this chapter only discusses structural ceramics for room, high and ultra-high temperature applications; this will include discussing how the properties depend on the chemistry and nature of the bonding. In terms of processing, unlike metals and alloys where component size, shape and properties can all be tuned using post-processes such as mechanical working (e.g., rolling, forging and extrusion) or heat treatments, the synthesis and consolidation of ceramics are less straight forward. Hence it is important to select at the start the appropriate combination of synthesis and consolidation methods in order to obtain the required properties for ceramics and their composites and thus a range of different types of synthesis routes and consolidation methods are described herein. Since structure, texture and properties are all related to each other, important microstructural characterization techniques are also described for different types of ceramics and composites, albeit there is currently limited data available on texture effects for structural and thermostructural ceramics. Performance evaluation can be largely determined based on mechanical and physical properties and so key properties for structural applications are described, including thermal properties such as thermal conductivity, coefficient of thermal expansion (CTE), creep and thermal shock resistance, oxidation and ablation resistance.

Classification and Properties

Advanced structural ceramics have attracted attention in the scientific community for many decades. Compared with metals, ceramics have much higher hardness and service temperatures, often > 1200°C and, in some specific cases, up to around 3000°C. From this perspective, ceramics have advantageous properties, such as refractoriness, strength retention at elevated temperatures, high melting points, wear resistance and chemical inertness. As a result of such an attractive combination of properties, ceramics are considered as candidate materials for many structural applications at both room and elevated temperatures. The widespread use of ceramics has been limited, however, by their inherent brittleness and the difficulties associated with their fabrication, which typically demand very high temperatures and, for non-oxide ceramics, controlled atmospheres (Murthy, 2020a).

Classification of ceramics can be achieved in several different ways, for example, based on chemistry, properties or applications, Fig. 1. This chapter focuses on structural and thermostructural ceramics, which are defined by their applications in a wide variety of environments including wear, erosion, corrosion, ablation, high temperatures and irradiation, amongst others and including combinations of all of them. In general, the primary properties of structural/thermostructural ceramics are classified as physical, mechanical, thermal and nuclear; values are compared for different ceramics in Table 1. Many of the properties possessed by ceramics are associated with their “mixed” bonding, a combination of covalent and ionic and, sometimes, metallic. They consist of arrays of interconnected atoms; there are no discrete molecules. The majority of ceramics are compounds of metals or metalloids (B, Si) and non-metals (O, N, C). It is worth noting here that many of the important properties of ceramics are actually superior to many structural metals and alloys, including, for example, density (they are generally lower), melting point (they are generally higher), strength (generally higher but with brittle failure) and CTE (generally lower) as shown in Table 1. As just one example, the density of silicon carbide is $\sim 3.2 \text{ g cm}^{-3}$, which is around half of many structural metals and alloys, whilst its maximum use temperature, in non-oxidizing environments (which metals also generally need) can be as high as 1700°C. The reason that the majority of ceramics are brittle is due to the mixed ionic-covalent bonding that holds the constituent atoms together. According to the von Mises criterion, a minimum of five independent active slip systems is required for deformation/ductility (Basu and Balani, 2011) and since ceramics do not have these at room temperature, they are fundamentally brittle. Note that this is not always true at elevated temperatures, where there can be limited examples of plasticity. Ceramics are also much stronger in compression than

Fig. 1 Broad classification of ceramics based on type of applications.

in tension, whereas metals have comparable tensile and compressive strengths; this difference is important when ceramics are used for load-bearing applications (Kingery *et al.*, 1976).

A large number of ceramics are also stable in both harsh chemical and thermal environments. The need for high performance materials for energy, aerospace, automotive and industrial components that can operate in aggressive environments such as corrosive/ablative atmospheres, high or ultra-high temperatures, irradiation and erosion has led to a surge in research and development into the structural/thermostructural ceramics and their composites. Although most applications do not exceed, say, 1500°C, there are an increasing number of applications, including re-entry space vehicles and hypersonic platforms, that are required to operate at temperatures of up to 3000°C and the ultra-high temperature ceramics, primarily transition metal carbides, borides and their composites, are candidates for these applications (Murthy, 2020b).

As well as the ceramics themselves, there are a range of composites that are based on reinforcing the host matrix, allowing these ceramics to be classified into six groups based on their microstructures, Fig. 2. More details on the microstructural aspects of these ceramics are discussed in the microstructure section; suffice it to say here that the use of reinforcement can significantly increase the toughness of these materials, adding this property to the generally very beneficial properties possessed by monolithic structural and thermostructural ceramics.

Applications

Ceramics are often used in preference to metals for one or more reasons, including, typically, to allow performance under more demanding conditions in order to enhance component life or safety, or to increase the efficiency of an existing process or reduce fuel consumption, especially for the transport sector, and, more recently, to reduce global warming. A variety of applications where structural and thermostructural ceramics and their composites are used are discussed below:

1. *Wear resistance and tribological applications:* The key properties for these applications are hardness, hot hardness, high melting point, elastic modulus, chemical inertness and corrosion resistance. As a result, applications include such items as: cutting tools, drills, thread guides, extrusion dies, wear tiles, grinding media, ball bearings and hybrid bearings (ceramic balls enclosed in a steel race), amongst many others. Whilst many of these applications are used extensively throughout a wide range of different industrial sectors, some are quite “high profile”, for example, hybrid bearings were used in the turbo pumps of the space shuttle main engines (Binner *et al.*, 2020).

Alumina, Al_2O_3 , has the highest hardness (up to 23 GPa) amongst the oxides and is also one of the cheaper advanced ceramics and so it is used extensively for its wear, erosion and impact resistance (Abyzov, 2019a). Silicon carbide, SiC (hardness up to 30 GPa), and boron carbide, B_4C (hardness up to 37 GPa and third hardest material after diamond and cubic BN), are both harder than the hardest oxides and are therefore used in large tonnages as abrasives in grinding wheels, cutting wheels, lapping media, etc. (Suri *et al.*, 2010). Tungsten carbide-cobalt, WC-Co-based cermets are commercially available for crushing and grinding applications, whilst the friction and wear properties of Al_2O_3 , zirconia, ZrO_2 , and SiC have been shown to be very useful for cryo-tribological applications (Guha and Basu, 2010). Ceramic balls for ball bearings are commercially available with diameters from 4 mm to as large as 20–30 mm and can be made from Al_2O_3 , ZrO_2 , SiC, B_4C , WC, silicon nitride, Si_3N_4 , and SiAlON, the latter being an “alloy” of Al_2O_3 and Si_3N_4 . ZrO_2 -based ceramics are increasingly being favored for applications ranging from kitchen knives to large industrial slitting knives, to room temperature metal extrusion and drawing dies. Other carbides, e.g., titanium carbide, TiC-based cermets are also used extensively as cutting tools.

Table 1 Important physical, mechanical, thermal and nuclear properties of selected structural/thermostructural ceramics

Fig. 2 Classification of structural/thermostructural ceramics based on their microstructures.

2. *Automobile and other metal-based industries:* The key properties for these applications are refractoriness, hardness, high melting point, chemical inertness and liquid metal corrosion resistance since applications include widespread uses as refractories for steel and nonferrous metals/alloy-making industries, including heating elements, roller hearths, thermocouple tubes and rollers for glass annealing kilns. Alumina, silica, magnesia, mullite, zirconia, cordierite and spinel are widely used refractories for different temperatures and conditions due to their high melting points $> 1800^{\circ}\text{C}$ (Table 1). In addition, ceramics find applications in electrical/thermal insulation, tubes, sheaths, molten metal crucibles and thermowell tubes in the steel refinement process. There are also increasing applications in automobile valves, exhaust systems, gears, valve guides & seals, engine tappets, turbocharger rotors, seals and bearings involving fluid and gas transport, which typically operate under quite corrosive conditions. Ceramics are also used for extrusion dies, cylinder liners, evaporation boats for vapor coating of aluminum, electrodes in Hall-Heroult cells, alkali metal thermoelectric converters and electric discharge machining (EDM) (Abyzov, 2019a,b). Commercial springs made of Si_3N_4 , which has a high elastic modulus of up to 330 GPa, Table 1, are also now available (Hampshire, 2007, 2008).
3. *Ceramic based coatings:* The key properties for these applications are hardness, high melting point, chemical inertness, wear, corrosion and ablation resistance with a wide range of applications including thermal barrier coatings (TBC), environmental barrier coatings (EBC), wear resistant coatings and corrosion resistant coatings. In addition, coatings are often used in the production and repair of a wide range of service components, including turbine blades, exhaust manifolds, nuclear equipment, valve and pump parts, grinding rollers, heat exchangers, jet engine parts, evaporators, chemical processing equipment and parts that are exposed to marine and other demanding environments (Abyzov, 2019a). Coatings are frequently made from carbides, nitrides, silicides, silicates and/or borides with coating thicknesses normally ranging between 1 and 50 μm , depending on the requirements of the application and the deposition process used (Krenkel *et al.*, 2006). Thicker coatings, e.g., in the millimeter range, can be applied by techniques such as thermal spraying but are limited in chemistry, compatibility with the substrate properties (e.g., thermal expansion, etc.), adhesion and cohesion (Basu and Balani, 2011). In recent years there has been a major focus on developing EBCs for the aerospace industry and other applications, with four different generations having been developed. The most recent, 4th generation, which mainly consists of rare earth silicates with oxide ceramics (zirconia & alumina), can withstand at least 1500°C (Krenkel *et al.*, 2006).
4. *Defense applications:* The key properties for these applications are high hardness, the Hugoniot Elastic Limit (HEL), wear resistance, lightweight and low thermal expansion coefficient, with a primary application being armor, whether for personnel, helicopter or tank and with transparent armor being used for windows (Suri *et al.*, 2010). In addition, ceramics are used for radar transparent missile nose cones and for hypervelocity platforms, e.g., missiles and rockets (Binner *et al.*, 2020). Over more than three decades, ballistic performance and dynamic behavior studies have been performed on a range of ceramics, including aluminum nitride, AlN , Al_2O_3 , B_4C , SiC , titanium diboride, TiB_2 , WC and ZrO_2 . Among these, B_4C in particular is used at the commercial scale for body armor due to its low density, 2.52 g cm^{-3} , and high HEL. Fully sintered silica is used for missile cones, whilst the ultra-high temperature ceramics and their composites are being extensively researched for hypervelocity applications (Binner *et al.*, 2020).
5. *Nuclear Applications:* The key properties for these applications are a low neutron absorption cross section for structural applications, a high neutron absorption cross section for control rod/shielding applications and irradiation resistance for both. Applications range from neutron absorbers, control rods and neutron shielding materials, fuel rod cladding tubes, irradiation shields for different types of sensors, reactor core components and structural materials for generation IV nuclear reactors. There are also a number of structural components and coatings used in fusion reactors, especially first wall and tokamak divertors. SiC and ZrC are both candidate structural materials in high temperature nuclear reactors due to their resistance to irradiation damage and low neutron absorption cross section (~ 0.9 barns), whilst B_4C is one of the most important materials for nuclear reactor applications. It is used as a control rod material for nuclear reactors due to the presence of the neutron absorbing ^{10}B isotope in natural boron and a resulting high neutron absorption cross section of ~ 600 barns (Florez *et al.*, 2020; Subramanian *et al.*, 2010).

6. *High and ultra-high temperature applications:* The key properties for these applications are a high melting point, thermal conductivity and wear resistance, a low coefficient of thermal expansion, excellent corrosion and/or ablation resistance as well as strength retention at elevated temperatures, good thermal shock resistance and, for some applications, low mass. The components (and their oxidized products if applicable) should be stable as solid phases at elevated temperatures, which can potentially be $\geq 2000^\circ\text{C}$. These structural and thermostructural ceramics are used for a range of aerospace and aeronautical applications, such as engine parts, including high pressure turbine shrouds, exhaust nozzles, combustor liners, turbine blades and vanes, rocket motors, bearing seals, plasma arc electrodes, heaters and igniters, leading edges, nose caps, and, for the highest temperature applications where operating temperatures can exceed 3000°C , hypersonic and scramjet platforms (Binner *et al.*, 2020; Paul *et al.*, 2016, 2014; Rubio *et al.*, 2018). Carbides and borides of Zr, Hf and Ta are the candidate materials for these applications due to their high melting points of $> 3000^\circ\text{C}$, low CTE of $\sim 10^{-6} \text{ K}^{-1}$ and good thermal shock resistance, Table 1.

Synthesis

A variety of synthesis methods have been explored by researchers around the world based on the requirements of the application, i.e. the properties desired, and the need for commercial viability, e.g., the quantities required (Fahrenholtz *et al.*, 2016; Sonber *et al.*, 2013). The successful application of ceramic components starts with the careful selection and optimization of the initial raw materials, i.e., the powder chemistry, purity, particle shape, size and its distribution, its specific surface area, degree of homogeneity, and, not least, its cost. All this necessitates choosing the right synthesis method, some of which are summarized in Table 2 (Murthy, 2020a; Sonber *et al.*, 2013). Subsequently, this is followed by a need to select the appropriate green forming and densification route; both the latter are discussed in the section on densification/consolidation.

Chemical methods

Many of the minerals that can be processed into oxide ceramics are naturally occurring in the earth's crust. They are extracted from the associated gangue by one or more of a range of mineral processing steps that are typically selected to deliver the required quantity with the required purity and particle size (Abyzov, 2019a). As one example, alumina is almost always obtained using the Bayer process, which involves extraction from bauxite – a mineral that mainly consists of the hydrated forms of Al_2O_3 , including gibbsite ($\text{Al}(\text{OH})_3$), boehmite and diasporite (Abyzov, 2019a). The bauxite ore is crushed and treated with strongly alkaline solutions of $\text{Na}(\text{OH})$ and $\text{Ca}(\text{OH})_2$. In the first stage, the aluminum hydroxides are converted into sodium aluminate NaAlO_2 and the silica present is also dissolved, whilst the CaO , Fe_2O_3 and TiO_2 impurities remain as part of an insoluble residue, which can be easily removed. The silica is subsequently also removed by slow heating, which causes a $\text{Na}_2\text{Si}(\text{OH})_6$ precipitate to form. The remaining clear solution of $\text{NaAl}(\text{OH})_4$ is cooled, diluted with water and neutralized with carbon dioxide. As a result, aluminum trihydrate, $\text{Al}(\text{OH})_3$, is selectively precipitated from the solution without any dissolved silica residues. The $\text{Al}(\text{OH})_3$ is calcined to yield anhydrous Al_2O_3 , the quality of which varies quite significantly depending on the baking conditions. At low temperatures ($300\text{--}800^\circ\text{C}$), metastable, transitional crystalline forms of Al_2O_3 are formed (e.g., δ , γ , η , κ , χ and θ - Al_2O_3), whilst higher temperatures, e.g., $1000\text{--}1300^\circ\text{C}$, yield α - Al_2O_3 , or corundum (Abyzov, 2019a). The main impurity in Al_2O_3 produced by the Bayer process is sodium, which is one of the worst contaminants for alumina ceramics and, if present in too large quantities limits the number of technical applications. This was one of the major issues in the early days of advanced ceramics, when demand for the material was too low to justify removing enough of the sodium. However, these days halogen-containing compounds such as BCl_3 are used to remove the sodium in the form of volatile NaCl by evaporation. The crystallite size of the α - Al_2O_3 typically varies from 0.5 to $10 \mu\text{m}$, with higher baking temperatures yielding coarser alumina (Abyzov, 2019a). These days, the drive is very much towards finer particle sizes since these yield finer grain sizes in the final ceramics, which can lead to superior properties such as strength though at the expense of a more expensive powder.

Other chemical methods to obtain oxide powders include hydroxide coprecipitation (Abyzov, 2019b), alkoxide hydrolysis, gel precipitation microemulsion, sol-gel (Xiong *et al.*, 2017), gas phase reaction and hydrothermal synthesis (Dell'agli & Mascolo, 2000). The first and last of these methods are currently exploited in large scale commercial production, whilst the others are typically either used for small scale production or are still in the laboratory. The co-precipitation method can be used, for example, to synthesize homogeneously distributed Y_2O_3 -doped ZrO_2 powders. The process involves using ammonia to leach ZrOCl_2 and $\text{YCl}_3/\text{Y}(\text{NO}_3)_3$ solution. A co-precipitation route has also been used to produce, nano crystalline, ZrO_2 by using KOH as precipitating agent (Ramachandran *et al.*, 2018). Hydrothermal synthesis is simple and cheap and is typically used to form nano crystalline and agglomerate-free oxide or mixed oxide powders at relatively low temperatures. For example, fine ZrO_2 - Y_2O_3 solid solutions have been prepared by using the precursors of zirconia gel, crystalline Y_2O_3 and Na_2CO_3 and NaOH solutions at a temperature of 110°C . A high pH value was obtained due to the hydrolysis of the Na_2CO_3 , often called a mineralizer, which helped to structurally rearrange the zirconia gel during the crystallization enabling the production of nano-sized particles (Dell'agli & Mascolo, 2000).

Indeed, a significant recent trend has been to find synthesis routes that will yield nanostructured powders since these can yield enhanced properties, not just increased strength but also transparency or other specialist properties in some cases. The sol-gel technique is a much investigated route to synthesize nanoparticles using a range of different precursors (Kumar *et al.*, 2015) since it requires low temperatures and has proven to be flexible and less complex compared to other routes for nanoparticle synthesis. The initial step is typically to convert the precursor material, often chlorides or metal alkoxides, into a colloidal solution, known as a sol, usually via hydrolysis. The latter is then converted, often via dehydration, into a gel, which is made up of discrete particles. The limitations of the sol-gel method are its expensive raw materials, the often poor yield and the fact that the processes involved are

Table 2 Important chemical reactions involved in the different types of synthesis of non-oxide structural/thermostructural ceramics

Type of synthesis reaction	Reaction number
I. Direct elemental/solid state reaction method

a. Carbothermic	
$MO_{2(s)} + B_2O_{3(l)} + 5C_{(s)} \rightarrow MB_{2(s)} + 5CO_{(g)}$	(16)
$MO_{2(s)} + 3C_{(s)} \rightarrow MC_{(s)} + 2CO_{(g)}$	(17)
b. Carbothermic in the presence of Boron carbide	
$2MO_{2(s)} + B_4C_{(s)} + 3C_{(s)} \rightarrow 2MB_{2(s)} + 4CO_{(g)}$	(18)
c. Borothermic	
$3MO_{2(s)} + 10B_{(s)} \rightarrow 3MB_{2(s)} + 2B_2O_{3(l/g)}$	(19)
d. Carbo and borothermic reduction	
$7MO_{2(s)} + 5B_4C_{(s)} \rightarrow 7MB_{2(s)} + 3B_2O_{3(l/g)} + 5CO_{(g)}$	(20)
e. Metallothermic reduction	
$3MO_{2(s)} + 3B_2O_{3(l)} + 10Al_{(l)} \rightarrow 3MB_{2(s)} + 5Al_2O_{3(s)}$	(21)
$MO_{2(s)} + B_2O_{3(l)} + 5Mg_{(l)} \rightarrow MB_{2(s)} + 5MgO_{(s)}$	(22)
f. Silicothermic reduction	
$MO_{2(s)} + 2Si_{(s)} \rightarrow MSi_{2(s)} + 4SiO_{(g)}$	(23)
g. Other reduction methods	
$MO_{2(s)} + B_2O_{3(s)} \xrightarrow{a} MB_{2(s)} + 5/2O_{2(g)}$	(24)
III. Chloride reduction/chemical synthesis methods	
$MCl_{4(g)} + 2BCl_{3(g)} + 5H_{2(s)} \rightarrow MB_{2(s)} + 10HCl_{(g)}$	(25)
$2MCl_{4(g)} + 8LiBH_{4(g)} \rightarrow 2MB_{2(s)} + 2B_2H_{6(g)} + 10H_{2(g)} + 8LiCl_{(g)}$	(26)
$MCl_{4(g)} + 2NaBH_{4(g)} \rightarrow MB_{2(s)} + 2NaCl_{(s)} + 4H_{2(g)} + Cl_{2(g)}$	(27)
IV. Displacement reaction method (suitable for making composite powders)	
$MC_{(s)} + 6B_{(s)} \rightarrow MB_{2(s)} + B_4C_{(s)}$	(28)
$2MC_{(s)} + B_4C_{(s)} + 3Si_{(s)} \rightarrow 2MB_{2(s)} + 3SiC_{(s)}$	(29)
$MN_{(s)} + B_{(s)} \rightarrow MB_{2(s)} + BN_{(s)}$	(30)
$4MN_{(s)} + 3B_4C_{(s)} + 3Si_{(s)} \rightarrow 4MB_{2(s)} + 3SiC_{(s)} + 4BN_{(s)}$	(31)

^ain the presence of catalyst 'CaO+CaF₂'; 'M' - Refractory/transition/rare earth metal, 's' - solid, 'l' - liquid, 'g' - gas, 'O' - oxygen, 'C' - carbon, 'N' - nitrogen.

often slow and energy-intensive, particularly for large scale production. Nevertheless, the method has been used for producing Al₂O₃, SiO₂, TiO₂, rare earth oxides and metal silicates, amongst other oxides (Kumar *et al.*, 2015).

Non-oxide ceramics are also produced by the sol-gel method, although they are not as easy to achieve. As just one example, nanocrystalline ZrC has been prepared by using zirconium *n*-propoxide and furfuryl alcohol as the precursors with a block copolymer P123 (Pluronic P123 is a symmetric triblock copolymer comprising poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO) in an alternating linear fashion, PEO-PPO-PEO) surfactant being used to achieve intimate mixing (Mallick *et al.*, 2016). Formation of ZrC starts at 1250°C and full conversion takes place at 1450°C but requires an argon atmosphere.

Direct elemental, self-propagating high temperature synthesis (SHS), mechanical alloying and shock-wave reaction methods

All these methods are typically used to produce non-oxide ceramics. The direct elemental reaction method represents the reaction between the respective metallic and/or non-metallic elements to form the desired ceramic, for example Ti, Zr, Hf, Nb are directly reacted with elemental carbon, boron or silicon in the stoichiometric ratio to form the respective carbides, borides or silicides

(SiC, TiC, ZrC, TiB₂, ZrB₂, HfB₂, MoSi₂, TiSi₂, ZrSi₂) at elevated temperature in a vacuum or inert atmosphere as shown in reactions 1–3 in Table 2. The advantages of this method are the ability to obtain highly pure and stoichiometric/near-stoichiometric products with fine particle/crystal sizes. However, this method requires expensive and pyrophoric-natured elemental powders, which, in turn, need extensive care to handle and store. For example, the synthesis of boron carbide from its elements is expensive due to the high cost of elemental boron and hence is employed for specialized nuclear applications only, such as B¹⁰-enriched or very pure/near-stoichiometric B₄C. Since the latter is in equilibrium with free carbon and is the only boundary between B_nC and B_nC + C (where 4 < n < 10), the synthesis of B₄C without free carbon is extremely difficult. With a view to producing B₄C, however, various experiments have been reported in which the B/C ratio was varied from 4.0 to 4.6 (Sonber *et al.*, 2013; Suri *et al.*, 2010). Whilst the B₄C phase could be obtained when the B/C ratio was 4.0, i.e., stoichiometric, the boron-rich B₈C phase was also present with the higher B/C ratios. Similarly, single phase niobium diboride, NbB₂, powder has been prepared by direct reaction of Nb and amorphous B powders (Murthy, 2020a) whilst molybdenum disilicide, MoSi₂, was synthesized from its elements using stoichiometric amounts of pure Mo (> 99.7%) and Si (> 99%) in a moderate vacuum of 0.1 Pa up to a temperature of 1400°C. Metal hydrides can also be used as starting materials instead of expensive elemental metals as per the reactions 4–6 in Table 2 to obtain similar purity products. Moreover, this approach can also produce composite powders, as per reactions 7–15 in Table 2. Nano-crystalline ZrC, for example, has been prepared by fast exothermic solid state metathesis reactions between CaC₂ and ZrCl₄ (Mallick *et al.*, 2016).

Self-propagating high-temperature synthesis (SHS) is an energy efficient method that can create phase pure, non-oxide ceramic powders in seconds via highly exothermic reactions of a reactant mixture. The temperature of the combustion can be extremely high, up to ~5000K, whilst the rate of wave propagation can be very rapid, e.g., 25 cm s⁻¹ (Mallick *et al.*, 2016). The key additional benefit of this method is the ability to obtain high purity, porous products due to the evaporation of the volatile impurities – the porous nature makes the crushing and grinding operations much easier leading to fine powders that contain few impurities from the grinding media. As an example, ZrC prepared by the SHS process using ball milled Al, Zr and C powders, the latter in the form of nano-sized carbon black. During the reaction, a metastable ZrAl₃ phase was formed and the heat released by this reaction was utilized to form the ZrC (Mallick *et al.*, 2016). ~26 nm TiB₂ powder has been produced via an SHS process using 20 wt% NaCl as a diluent (Gadaky *et al.*, 2014) whilst ZrB₂ has been formed from the elemental powders via a thermodynamically favorable reaction; $\Delta G_{2000K} - 279.6 \text{ kJ mol}^{-1}$. ZrB₂-based cermets were also prepared by the SHS route using ZrO₂, B₂O₃ and excess Al as reactants together with Fe₂O₃. Meanwhile ZrB₂-ZrC composite powders were synthesized by a mechanical activation-assisted SHS process using a mixture of Zr, B and C powders (Sonber *et al.*, 2013).

Mechanical alloying (MA) is a solid-state powder processing technique involving high energy ball milling, often for prolonged durations. Submicron-sized TiB₂ powder has been prepared from a mixture of Ti and B powders (Hwang and Lee, 2002). It was reported that the size of the metal powder and the heat of formation of the boride greatly affected the mechanical alloying time, whilst leading to fine boride compound powders. The room temperature MA of B–C mixtures in planetary ball mills for prolonged duration, which was said to activate the powders, was followed by an annealing heat treatment that lead to B₄C powders, which were subsequently densified by spark plasma sintering to yield 95% pure boron carbide ceramics (Heian *et al.*, 2004). Spark plasma synthesis is a process in which a pulsed high DC current is passed through the charge mixture, which is contained in a cavity, along with the simultaneous application of uniaxial pressure. In this process for B₄C, the start and completion of formation were reported at 1000 and 1200°C respectively. Finally, ZrB₂ with a crystallite size of ~75 nm was also prepared successfully by mechanical alloying of ZrO₂, B₂O₃ and Mg for 15 h (Sonber *et al.*, 2013).

Finally, the shock wave (SW) technique is based on achieving very high heating and cooling rates along with a simultaneous high pressure. This is accomplished by placing the reactants inside a steel container, which, in turn, is placed inside a steel tube. An electric detonator is placed between a container and the tube to initiate an explosive detonation that occurs in micro to milliseconds. After the resulting shock treatment, the samples were recovered by shaving off the steel container with a lathe (Suri *et al.*, 2010). This approach is suitable for the preparation of crystals of non-equilibrium phases that are hard to be produced under conditions of thermal equilibrium. The approach has been used to synthesize boron carbide from amorphous boron and graphite powder using trimethylenetrinitramine as the detonator. The resultant product exhibited several different morphologies, such as filaments, distorted ellipsoids, plates and nano-sized polyhedron particles.

Oxide reduction methods (carbothermic, borothermic, metallothermic and silicothermic)

Carbothermal reduction of the corresponding transition or refractory metal oxides emerged as an economical production route and continues to be the most popular method for the synthesis of commercial carbide and boride powders as per reactions 16–18 in Table 2. The resulting powders typically contain oxygen and excess carbon as impurities (up to 1%) along with other metallic impurities that are present in the starting raw materials. For example, commercial ZrB₂ is produced from naturally occurring zircon ores, which usually contain Hf as an impurity. In addition, although it is possible to reduce some impurities, particularly carbon and oxygen, to ppm level by an appropriate high temperature vacuum treatment, impurities, including the reintroduction of oxygen, can be picked up during grinding, both from the media used and the atmosphere (Fahrenholtz *et al.*, 2016). Although this route is commercially viable, all process parameters have to be carefully optimized to yield both the desired phase and the required particle size. Other metal oxide reduction methods such as borothermic, metallothermic and silicothermic reduction processes, though far less common, are also attractive for commercial production of some non-oxide ceramics at the industrial scale, as shown in Table 2, reactions 16–24. A few case studies are summarized below.

B₄C powder has been synthesized at 1200°C by the carbothermal reduction of boric acid with petroleum coke and also by the magnesiothermic reduction of B₂O₃ or alkali Na₂B₄O₇ in the presence of carbon at 1650–1700°C (Gunnewiek *et al.*, 2017). The addition of metallic sulfates, which act as a catalyst, allows the temperature to be reduced to as low as 700°C. Nano ZrC powder with only 0.1 wt% O₂ impurity was synthesized by the reduction of ZrO₂ with carbon in an argon atmosphere at 1800°C (Mallick *et al.*, 2016) whilst pure WC nanopowder, ~7 nm particle size, was prepared by the mechanical solid-state reduction of WO₃ and Mg followed by the solid-state reaction of W and C using high-energy ball milling (HEBM).

ZrB₂ powder is typically synthesized as per reaction 18 in Table 2 at a temperature of > 1800°C in a dynamic vacuum or inert atmosphere; the former yields faster kinetics and results in a higher purity product (Murthy, 2020a). The borothermal reduction of ZrO₂ can yield pure ZrB₂ at temperatures higher than 1600°C, though the method is not economic for commercial production as it involves the volatilization of expensive boron in the form of boron oxide (Sonber *et al.*, 2013). The carbothermal reduction of zirconia and boric acid with carbon has also been used to synthesize ZrB₂ whiskers. Meanwhile, ZrB₂, TiB₂ and HfB₂ powders have all been synthesized by the borothermal reaction between the respective metal dioxides and elemental boron in the range 1000–1750°C under vacuum (Jung *et al.*, 2012). The morphology and particle size of the powders was strongly influenced by the synthesis temperature; a faceted morphology and diameter of ~0.15 µm was reported between 1000 and 1200°C whilst a spherical morphology with a particle size of ~0.66 µm was observed at > 1500°C. Guo and Zhang (2009) reported that they generally formed ZrC along with ZrB₂ when using additions of boron carbide during the reduction; however they obtained single phase ZrB₂ by using an excess of 20–25 wt% B₄C; this will have covered for the volatilization of the boron.

The metallothermic reduction of ZrO₂ and B₂O₃ (as for all of these processes, excess B₂O₃ is required) involves the use of cheap raw materials and is self-sustainable due to its exothermic, self-propagating high temperature synthesis, nature. Generally, magnesium, aluminum, calcium, sodium or silicon are used as reducing agents for metallothermic reductions; of these magnesium is usually preferred due to the relative ease of leaching out its oxide form from the product. During this process, the complete consumption of the reactants has to be ensured, especially the ZrO₂ since it is very difficult to remove any excess from the product by leaching or dissolution due to its refractory nature (Sonber *et al.*, 2013). Aluminum was used as the reducing agent for the preparation of ZrB₂-Al₂O₃ composite powders as per reaction 21 in Table 2. Several different precursor mixtures have been used during the synthesis of TiB₂ by carbothermic reduction, including the mixed oxides of boron and titanium, the reduction of titanium oxide by mixtures of boron carbide and carbon, and the reduction of the mixed oxides by metals, including aluminum, silicon and magnesium (Fahrenholtz *et al.*, 2016). Meanwhile HfB₂ has also been synthesized by borothermic reduction, carbothermic and metallothermic reduction (Murthy, 2020a; Sonber *et al.*, 2013). NbB₂ has been prepared by borothermic reduction of Nb₂O₅ in a vacuum and also by melting a mixture of Nb₂O₅ and B in an argon plasma arc (Yeh and Chen, 2006). CrB₂ and other refractory metal borides have also been synthesized by a range of different reduction methods as per the reactions 16–24 in Table 2.

Gas phase reactions and other methods of synthesis

Other methods of synthesis include gas phase, solution-based, molten salt electrolysis and polymer-precursor methods. These approaches generally enable the production of ultra-fine powders with very high purity, but suffer from the limitations of being expensive with low productivity and often involving the handling of toxic or explosive gases or solutions.

The solution-based methods involve intimate contact between the reactants in a liquid state and hence require only low temperatures (Sonber *et al.*, 2013). ~200 nm ZrB₂ powders with a specific surface area of 32 m²g⁻¹ were prepared by using inorganic-organic hybrid precursors of zirconium oxychloride (ZrOCl₂·8H₂O), boric acid and phenolic resin as sources of zirconia, boron oxide and carbon respectively at the relatively low temperature of 1500°C. ZrB₂ has also been synthesized using zirconium *n*-propoxide refluxed with 2,4-pentanedione to form zirconium diketonate. This compound further hydrolyzed in a controllable fashion to form a zirconia precursor that, with boric acid and phenol-formaldehyde, was concentrated, dried, pyrolyzed at 800–1100°C, and then carbothermally reduced at 1150–1800°C to yield spherical particles of 200–600 nm ZrB₂ (Murthy, 2020a). Even finer, 5–100 nm, TiB₂ has been prepared using a solution phase reaction between NaBH₄ and TiCl₄, followed by annealing the amorphous precursor obtained at 900–1100°C (Khoshshima *et al.*, 2020).

Various non-oxide ceramics have been synthesized by the molten salt electrolysis method (Sonber *et al.*, 2013). ZrB₂ was deposited from a solution of ZrO₂ and B₂O₃ dissolved in molten Na₃AlF₆ at 1020°C on nickel cathodes using a graphite anode. The resultant ZrB₂ was reported to be scaly/dendritic and non-adherent. ZrB₂ has also deposited on nickel cathodes from cryolite-alumina melts containing zirconium and boron oxide. Meanwhile CrB₂ nanorods were prepared via a reduction-boronation route at 650°C in a molten salt of anhydrous aluminum trichloride using an autoclave. Many other rare earth hexaborides have also been prepared using the molten salt electrolysis method (Berchmans *et al.*, 2010).

The polymer precursor method for synthesizing of non-oxide ceramics is typically performed by dispersing a metal oxide in a boron carbide-polymeric precursor. On heating, the mixture results in the in-situ generation of boron carbide and carbon, which provide the source of B and C, followed by a reaction to produce the non-oxide ceramics by reduction of the appropriate metal oxide. The desired characteristics of the polymer are that it should contain the required elements to form the intended non-oxide ceramic compound by the reduction of the metal oxide but also be stable and “processable”. Dinitrile polymers are one of the examples which have the required characteristics and provide a good yield when used to form borides from the condensation polymerization of deca-borane (Sonber *et al.*, 2013). Crystalline ZrB₂ has been prepared by dispersing ZrO₂ into polymer precursor decaborane dicyanopentane polymer (-B₁₀H₁₂-NC-(CH₂)₅-CN-)_x and pyrolysing at 1450°C (Forsthoefer and Sneddon, 2004). Displacement reactions are another common method used for the in-situ synthesis of ceramics and composites powders as per reactions 28–31, Table 2. These reactions offer the same advantages as direct synthesis reactions, viz., low temperature

requirements, high purity and control of particle morphology, but often use less costly or more stable precursors. HfB_2 powders containing 22 vol% SiC and 5 vol% ZrC were synthesized below 1200°C from a mixture of Hf, Si and B_4C (Forsthoefel and Sneddon, 2004).

The nitridation reaction can be used to synthesize nitride ceramics, for example, porous solid reaction bonded silicon nitride (RBSN) is formed by reacting silicon powder with nitrogen gas at $> 1000^\circ\text{C}$. The porous solid can then be ground into a fine powder using standard milling techniques. Chemical vapor deposition can also be used to deposit nitride coatings by reacting metal chlorides, e.g., silicon tetrachloride, with ammonia. The product, in this case silicon nitride, Si_3N_4 , is usually obtained in an amorphous state, but it can be crystallized by a heat treatment at a higher temperature such as $\sim 1300^\circ\text{C}$. The carbothermal reduction of metal oxides with carbon in the presence of high pressure nitrogen also yields nitride powders. For example, Si_3N_4 can also be obtained by reducing SiO_2 with petroleum or active coke in a nitrogen atmosphere. The process requires excess carbon in order to ensure complete reduction of the SiO_2 . Any residual carbon is subsequently burned off at temperatures of $\geq 550^\circ\text{C}$. SiO and SiC can also be formed during this process unless the composition and temperature are carefully controlled (Hampshire, 2007, 2008).

Densification/Consolidation

A number of different fabrication methods are listed in Table 3, each with a representative schematic and the advantages and limitations of each method are also outlined. Sintering can be accomplished via pressureless sintering – typically used for the oxide-based materials, or, more commonly, by using external pressure (e.g., hot pressing, hot isostatic pressing or spark plasma sintering). There are also a range of newer techniques, including microwave sintering and flash sintering where the use of conventional furnaces is replaced by alternative energy sources.

The pressure-based approaches are often used for the non-oxides since pressureless sintering rarely yields a sufficiently high density due to the high melting point, strong covalent bonding and low intrinsic self-diffusivity of the ceramics (Fahrenholtz *et al.*, 2014). Higher temperatures can be used for densification by pressureless sintering techniques, but this tends to lead to exaggerated grain growth, which results in poor mechanical properties due to the formation of micro cracks at the grain boundaries (Suri *et al.*, 2010). In addition, non-oxide ceramic powder surfaces are always contaminated with surface oxides, which promote surface diffusion and evaporation condensation mechanisms (Basu *et al.*, 2006). To achieve high densities whilst inhibiting abnormal grain growth, it has been recommended that the total oxygen content of the powder must be limited to ≤ 0.5 wt% or strong reducing additives need to be used to remove the surface oxides (Murthy, 2012). Other possible solutions to overcome these limitations include using nanosized starting powders, or using reactive sintering, liquid phase sintering, cement-bonded sintering as well as the pressure-assisted sintering techniques mentioned above. Sintering additives can enhance the densification and hence properties of the end product due to one or more mechanisms, including (1) the formation of a liquid phase at the sintering temperature (liquid phase sintering), (2) the reduction of the surface oxides, (3) an increase in the defect concentration due to chemical reactions (reactive sintering) or (4) the stabilization of high temperature phases (Murthy, 2020a; Sonber *et al.*, 2013). A range of additives have been exploited to improve the sinterability and properties of the non-oxide structural ceramics, including metallic additions, e.g., Ni, Fe, Cu, Co, Ti, and non-metallic, e.g., Y_2O_3 , CeO_2 , AlN, MoSi_2 , CrSi_2 , WSi_2 , TiSi_2 , SiC, Si_3N_4 , CrB_2 , B_4C , TaC, CNT, graphene (Alexander *et al.*, 2018; Binner *et al.*, 2020; Suri *et al.*, 2010). The choice of sinter additive is very important as they can also influence the mechanical, thermal, nuclear and oxidation properties.

Historically, the use of hot pressing or spark plasma sintering to create CMCs has typically resulted in damage to the continuous fibers due to the high sintering temperatures and pressures required. Hence, other non-sintering approaches such as polymer impregnation and pyrolysis (PIP), reactive melt infiltration (RMI) and chemical vapor infiltration (CVI) are also commonly adopted for fabricating CMCs (Binner *et al.*, 2020). The most commonly used approaches are reviewed below.

Pressureless sintering

Pressureless sintering is a very simple and economical technique to consolidate green components. The operation is carried out in two steps: (1) making the green compacts, which need to have sufficient handling strength, via one of many different approaches, including dry powder compaction, wet forming routes such as slip casting or plastic forming routes such as injection molding and then (2) densifying the green bodies by sintering at the required temperature in an appropriate atmosphere. Heating can be done in a resistance heating furnace or, less commonly, in an induction furnace; the latter is suitable for conductive/semi-conductive ceramics or else graphite/SiC susceptors can be used (Murthy, 2020a; Suri *et al.*, 2010). Multi wall carbon nano tubes (MWCNT)- Al_2O_3 composites, for example, have been prepared by pressureless sintering for 1–2 h at 1500–1600°C in argon though the final densities were reported to be poor (Akin and Goller, 2015). Similar work by sintering for 2 h at 1700°C in argon were reported to achieve a density of $\sim 99\%$ of theoretical (Akin and Goller, 2015). Silicon nitride powder compacts have been sintered at 1750–1900°C under a 0.1 MPa nitrogen atmosphere (Hampshire, 2007, 2008), with a relative density of $\sim 85\%$ being achieved whilst only 78% dense samples were obtained for monolithic ZrB_2 after 2 h at 2050°C (Sonber and Suri, 2011). In contrast, $\sim 98\%$ dense ZrB_2 was achieved by pressureless sintering at 2150°C for 9 h (Ma *et al.*, 2015). In the case of HfC, a maximum density of 90% of theoretical was reported after pressureless sintering for 2 h at 2760°C (Liu *et al.*, 2013) whilst 93.1% density was reported for TiB_2 after sintering at for 2 h 2150°C in argon and 93% density was achieved for CrB_2 after 6 h at 1850°C under vacuum. The use of liquid phase sintering additives can result in higher densities; ZrB_2 – SiC – MoSi_2 composites achieved 98.7% relative density after pressureless sintering for only 1 h at 2150°C (Mashhadi *et al.*, 2016).

Table 3 Densification/consolidation methods of structural/thermostructural ceramics by different methods

Type of method	Schematic/Mechanism	Advantages	Limitations
Pressureless sintering		● Fabrication of near net shape components which will drastically reduce expensive machining operations. ● Simple process and more economical	● It is extremely difficult to prepare sound dense shapes of non-oxide ceramics due to low self-diffusivity coefficient
Liquid phase/ Cement bonded/ Reactive sintering	 Rearrangement → Dissolution & Reprecipitation → Solid state Sintering → Grain growth	● Lower sintering temperature ● Fast densification ● High final densities and resulting microstructures often providing mechanical or physical material properties superior to solid state sintered materials	● High distortion ● Deterioration of mechanical properties due to the solidification of brittle/noncrystalline phases along grain boundaries and/or grain growth during sintering, Not suitable for high-temperature applications; ● This technique can be used only for a limited combination of materials
Hot Pressing (HP)	 [reprinted with permission from Handbook of Advanced Ceramics and Composites, Springer Nature Switzerland AG, 2019]	● High density achievable ● Grain growth can be minimised ● Often lower temperatures and time required compared to PS ● Apparatus is the same can be used for the PS or LPS ● Different 2D shapes can be manufactured ● Superior microstructures compared to PS	● Near-net shape components are not achievable ● Expensive initial investment, tooling materials and maintenance costs ● For CMCs: Matrix-fibre interaction and fibre degradation due to high temperature and pressure
Hot Isostatic pressing (HIP)		● High density achievable ● Grain growth can be minimised ● Often lower temperatures and time required compared to PS, HP ● Superior microstructures compared to PS & HP ● Near-net shapes are possible	● Equipment is more expensive than conventional HP and pressureless furnaces ● Usually works with high pressure ● Selection of suitable canning material ● For CMCs: Matrix-fibre interaction and fibre degradation due to high temperature and pressure
Spark plasma sintering (SPS)	 [reprinted with permission from Elsevier: Figure 4 in Sairam <i>et al.</i>, 2014. Influence of spark plasma sintering parameters on densification and mechanical properties of boron carbide. International Journal of Refractory Metals and Hard Materials 42, 185–192.]	● High density achievable ● Grain growth can be avoided ● Relatively low temperatures and time required compared to PS, HP ● Superior microstructures compared to PS & HP	● Near-net shape components are not achievable ● Expensive initial investment, tooling materials and maintenance costs ● For CMCs: Matrix-fibre interaction and fibre degradation due to high temperature and pressure

Table 3 Continued

Type of method	Schematic/Mechanism	Advantages	Limitations
Flash Sintering		● Rapid consolidation of ceramic powders ● Near theoretical density whilst retaining homogeneous fine grained microstructures ● Much lower temperatures than conventional	● Relatively new technique, demonstrated to only for lab scale ● Reproducibility ● Specialised equipment and expertise required ● Proven for only a few ceramics ● Near net shape is not feasible with the current technology
Microwave Sintering (MW)		● Uniform and rapid heating since the energy is directly coupled into the specimen rather than being conducted into the specimen from an external heat source like conventional resistance heating systems. ● Faster heating than conventional methods (PS, HP, HIP)	● Size limitation due to limited depth of penetration ● Compatible for only a limited materials
Ceramic Matrix composites (CMC) – continuous fibre reinforced composites		<u>RMI</u> ● A near fully dense matrix ● Processing time is short ● Relatively cheap <u>SIP</u> ● Cheap, quick and easy ● Simple procedure to introduce a slurry to a fibrous substrate ● Properties of the slurry are easily tuneable based on the chemicals used <u>PIP</u> ● Composition of the ceramic deposit is highly versatile due to chemistry of precursor ● A large degree of control of the physical properties of the precursor is obtainable again by tailoring the chemistry of the precursor ● Simple procedure <u>CVI</u> ● High purity, nano size, near stoichiometric deposition is possible ● Low temperature process, thus fibre damage can be avoided ● Intricate shapes can be prepared without damaging the continuous fibres	<u>RMI</u> ● Required high temperatures ● The exothermic nature of the reaction between constituents can increase the temperatures locally, causing more damage of the fibres (Liquid metal corrosion) ● Residual metallic phases, which have relatively low oxidation resistance and a lower melting point than the ceramic phases present. This metallic phase can lead to accelerated creep, crack propagation <u>SIP</u> ● Homogeneous penetration of large preforms is difficult ● Stable suspensions of dense ceramic particles are hard to make; possible issue with respect to scalability ● Issues exist with clogging the surface of preforms with ceramic particles <u>PIP</u> ● Low yields of ceramic from precursor will require many cycles of infiltration and pyrolysis

(Continued)

Table 3 Continued

Type of method	Schematic/Mechanism	Advantages	Limitations
			• The matrix will always be porous and micro-cracked, due to the escape of gaseous by-products and volumetric shrinkage from precursor to ceramic • Reactive chemicals and repeated heat treatments can cause fibre degradation or damage
			CVI
			• Processing times of industrial scale CVI is currently very long, on the order of 2–3 months, due to isothermal heating rates and premature surface porosity closure that requires the process to be stopped a number of times • Large energy input is required due to the extended process times • Corrosive by-products require special safety precautions, expensive equipment and maintenance costs are subsequently high • It is very difficult to obtain fully dense composites; densities of ~90% of theoretical are therefore typical

CVI – chemical vapour infiltration, PIP – precursor infiltration and pyrolysis, RMI – reactive melt infiltration, SIP – slurry impregnation process.

Hot pressing (HP)

Hot pressing is the most commonly used technique for fabricating dense, non-oxide monolithic ceramics and their composites (Suri *et al.*, 2010). During hot pressing, temperature and pressure are simultaneously applied to the powder compact contained in a die. Heating is usually achieved using induction coils and a graphite die, whilst the pressure is often applied hydraulically. Under the application of pressure, the contact points between particles develop a very high stress, increasing the local diffusion rates. As for all forms of densification, the particle size, temperature, pressure, heating rate and holding time all influence the density and microstructure of the hot pressed compacts whilst a controlled atmosphere is required for the non-oxides. Carbides, borides and silicides are often hot pressed under vacuum or an inert gas such as argon whilst the nitrides are generally densified under a nitrogen atmosphere. Often, the pressure is applied when the maximum sintering temperature is reached, though it can be increased at intervals as the temperature increases. As examples of the densities achieved via hot pressing, 90% of theoretical was obtained for Fe-Al₂O₃-(4–6 wt%) CNT composites by hot pressing for 15 min at 1500°C under 43 MPa (Akin and Goller, 2015); this compares favorably with what could be achieved by pressureless sintering. Fully dense Si₃N₄ was produced by hot pressing for 1 h at 1850°C and 23 MPa with magnesia as the additive (Hakeem *et al.*, 2014; Hampshire, 2007, 2008) whilst fully dense ZrB₂ required 1 h at 1900°C and 32 MPa (Chamberlain *et al.*, 2004). In contrast, only 80% of theoretical density was achieved by hot pressing HfB₂ for 2 h at 1850°C and 35 MPa, though CrB₂ has been reported to be fully dense by hot pressing for 2 h at 1700°C and 35 MPa (Bedse *et al.*, 2015; Sonber *et al.*, 2010). Further improvement in densification, as well as properties of the resulting non-oxide ceramics, have been reported after the addition of sintering additives such as metal or non-metal particles, including Nb, EuB₆ and MoSi₂, amongst others (Murthy, 2020a; Sonber *et al.*, 2013).

Spark plasma sintering (SPS)

SPS is a relatively new technique compared to hot pressing, although the approach is not intrinsically different. Typically, the powder to be consolidated is placed in a graphite die assembly, similar to that for a hot press, and then the heating source consists of passing a pulsed or direct current through the conductive die (Murthy, 2020a; Sairam *et al.*, 2014). A schematic is shown in Table 3. Note that the temperature is typically measured on the die surface, which will be much lower than the actual sample

temperature, the difference depending on factors such as the size of the die, the level of vacuum and the insulation used. The primary advantage of SPS over hot pressing is the very fast rate of heating achieved; this helps to achieve higher densities by the phenomenon of “fast firing” (Ji *et al.*, 2017); this particularly helps with retaining finer grain sizes, especially with finer powders that are more sinter-active (Hu *et al.*, 2020).

The densification mechanism during SPS has been debated and many theories and models are discussed in the literature (Hu *et al.*, 2020). Some of the key points are summarized here. One argument is that the current passes primarily through the die and it is the resulting very fast heating rate that leads to the higher densification achieved under similar conditions – or the ability to use lower temperatures/pressures and/or shorter times (Hu *et al.*, 2020). An alternative argument is that the driving force for densification is provided by the current passing through the powder, generating electrical discharges that activate the particle surfaces by evaporation of the oxide film (non-oxide ceramic particle surfaces are always contaminated with oxygen) and impurities (Ji *et al.*, 2017). Subsequently, bonding is accomplished by resistance heating at the contact points between the activated particles in the presence of high pressure. The time and temperature required for consolidation are lowered due to the combination of high current density and high shear, which leads to localized heating and plastic deformation at the interparticle contact points. The rapid sintering, which ideally lasts for less than a few minutes, prevents grain growth and allows the grain size to be not much larger than the original particle size (Hu *et al.*, 2020; Ji *et al.*, 2017). In terms of what has been achieved, nano- Al_2O_3 and nano- TiO_2 powders have been consolidated using SPS in just 3 mins at 1150°C and 63 MPa (Saheb *et al.*, 2019). Similarly, Al_2O_3 + (6–15 wt%) SWCNT (single walled carbon nanotubes) composites were densified after 3 mins at 1150–1200°C and 63 MPa (Akin and Goller, 2015). Fully dense nano SiAlON ceramics with a BaO additive required 30 mins at 1400°C and 50 MPa (Hakeem *et al.*, 2014) whilst fully dense AlN ceramics were prepared in 15–30 min at 1500–1600°C and 30–40 MPa and >98% dense Si_3N_4 ceramics required 5 min at 1500°C and 20 MPa (Belmonte *et al.*, 2010). Whilst higher temperatures are required for ceramics such as ZrB_2 , full density was obtained after just 3 mins at 1900°C and 50 MPa; the heating rate was 200–300°C min⁻¹ (Guo *et al.*, 2008). Conventional SPS was used to obtain 99% dense ZrB_2 –20% SiC composites in 5 mins at 2000°C and 20 MPa, whilst the combination of SPS with reactive sintering for the same composite was achieved using Zr, Si and B_4C in 9 mins at just 1400°C and 30 MPa (Zhao *et al.*, 2009). Finally, HfB_2 –20% SiC composites were densified to near theoretical density in 10 mins at 1850°C and 30 MPa using conventional SPS, whilst achieving 98.4% dense chromium diboride required 15 mins at 1900°C and 70 MPa (Mahesh *et al.*, 2015; Nisar and Balani, 2017).

Microwave sintering (MW)

Microwave sintering is a potential alternative to conventional densification techniques. In microwave sintering, heating of the ceramic powder compact is achieved by absorption of microwaves within the material to be sintered, although it should be noted that not all ceramics are good absorbers of microwaves. Ceramics such as zirconia, silicon carbide, zirconium and hafnium diboride do absorb microwaves whilst others, such as alumina or silicon nitride are largely transparent until the temperature reaches around 1000°C or higher (Oghbaei and Mirzaee, 2010). For ceramics that do absorb microwaves, the approach offers the potential advantage of rapid heating since the energy is directly coupled into the specimen, rather than being conducted into the specimen from an external heat source such as conventional resistance heating systems. Since the ceramic is the hottest part of the system, subsequent heat losses from the surface can result in an inverse temperature profile, i.e., the center of the body is hotter than the surface. This can offer significant advantages, especially for materials where there is a need to maintain a gas phase in contact with the powder particles as they sinter, for example, during the microwave reaction sintering of silicon metal powder into silicon nitride (Luo *et al.*, 2020). In general, the rapid nature of the sintering and the so-called “microwave effect” (where the ceramic densifies at a lower temperature and/or in a faster time than with conventional sintering) can result in finer microstructures for microwave sintered materials (Oghbaei and Mirzaee, 2010). This phenomenon has been rigorously investigated using hybrid sintering systems and found to be a consistent result (Wang *et al.*, 2006). As a result, research has shown microwave sintering can take <20% of the time required with conventional gas or electrically heated furnaces for similar products – and hence use only 20% of the energy (Bhattacharya and Tanmay, 2016).

Although many ceramics have been sintered successfully using purely microwave energy (Bhattacharya and Tanmay, 2016), there is evidence that a hybrid approach that combines microwaves and conventional energy can result in superior results (Binner *et al.*, 2008). Whilst most work focuses on using 2.45 GHz, there have been some attempts to use 28 GHz, though the depth of penetration is smaller, limiting the size of the samples (Luo *et al.*, 2020). Most work has focused on the densification of oxides; however non-oxides can also be successfully sintered, though a controlled atmosphere is also required. For example, TiB_2 has been rapidly sintered to >90% of theoretical in ≤ 30 mins at 1900–2100°C using 6 kW of 2.45 GHz microwave heating. A comparison with conventional sintering indicated that microwave sintering of TiB_2 + 3 wt% CrB_2 occurred at a temperature 200°C lower and yielded significantly improved hardness, grain size and fracture toughness.

Although as indicated above, not all ceramics absorb microwaves at room temperature, most will do so at elevated temperature. Thus, high purity alumina, which is transparent to microwaves at room temperature, will start to couple at typically >1000°C. It is therefore not unknown for additives to be introduced into ceramics that will absorb the microwaves at low temperature, knowing that once the temperature of the material gets high enough, the whole of the material will begin to absorb in its own right. For example, ZrB_2 + SiC composite has been fully densified at 1850°C, with the SiC providing the initial microwave absorption (Sharma and Karunakar, 2019).

Liquid phase sintering (LPS)

Like solid state sintering, liquid phase sintering is a densification mechanism rather than a sintering approach and hence can be used in combination with any of the other techniques described above (Kang, 2005). It is mentioned here in its own right because it is an

approach that is often used for the non-oxide ceramics that form the basis of many structural and thermostructural ceramics. It involves designing the ceramic's composition so that there is typically 5%–10% of liquid at the sintering temperature; this allows the ceramic particles to rearrange and, as importantly, for the atoms to dissolve, diffuse down concentration gradients and then reprecipitate at different points in the microstructure. This accelerates the densification process considerably compared to solid state sintering, though it can result in glassy grain boundary phases after the liquid present at the sintering temperature cools (Kang, 2005). As a result, liquid phase sintering is often used for densifying ceramics that are hard to densify by solid state sintering, e.g., the non-oxides. As an example, the addition of Mo to the TiC–Ni system decreases the contact angle from 30° to 0° (German *et al.*, 2009), allowing sintering to obtain the dense component. Like all silicon-based non-oxides, Si_3N_4 powder particles are contaminated with surface silica layers so additives such as MgO and Y_2O_3 will react with the silica and some of the nitride itself at the sintering temperature to form an oxynitride liquid that promotes liquid phase sintering. In addition, the equiaxed α - Si_3N_4 dissolves in the liquid and is precipitated as the acicular β - Si_3N_4 , which yields an interlocked microstructure that offers a higher toughness (Hampshire, 2007, 2008; Hampshire *et al.*, 1978).

Non-sintering based techniques

There are a number of densification techniques that do not rely on sintering; they are generally used for the densification of ceramic matrix composites, CMCs. Examples include reactive melt infiltration (RMI), precursor infiltration and pyrolysis (PIP) and chemical vapor infiltration (CVI). Each of these will be very briefly described in turn.

RMI is the introduction of molten metal, typically Si, Zr or Ti, into a porous ceramic fiber preform where it reacts in-situ with either a pre-matrix carbon or boron phase to form the desired ceramic compound, typically with a high matrix density (Binner *et al.*, 2020). This technique was industrialized for the mass production of SiC_f/SiC CMCs by General Electric for their advanced civilian aerospace engines (GE Aviation Fired up on CMCs, 2015). These CMCs were the first to be used commercially in the civil aviation industry on General Electric's CFM LEAP engines that were launched in 2016. Work on the formation of ultra-high temperature CMCs (UHTCMCs) based on ZrB_2 has also been undertaken using RMI by DLR (Johnson, Gasch and Stackpoole, 2009).

PIP is initially a green-forming procedure in which a liquid chemical precursor is impregnated into a reinforcement phase and then subsequently pyrolyzed at elevated temperatures. The pyrolysis reaction yields the required ceramic product, which is retained within the preform body (Binner *et al.*, 2020). Whilst very successful, the evolution of gaseous by-products and the consequent volume shrinkage as the precursor converts to the ceramic means that the process must be performed iteratively many times, often a dozen or more, until a matrix of the desired density is achieved. Once again, the process has been used for SiC , ZrB_2 , ZrC , HfC and HfB_2 ceramic based composites (Zhao *et al.*, 2017).

CVI is a well-established technique for the fabrication of fiber-reinforced ceramic matrix composites (FRCMCs) and, again, particularly for SiC_f/SiC CMCs (Vignoles, 1992). The main benefit is its ability to produce materials with attractive mechanical properties at relatively low processing temperatures, typically $\sim 1000^\circ\text{C}$, whilst avoiding the use of pressure, which reduces fiber stress and damage. CVI is a near-net shape process, which aids the production of irregular-shaped components for a wide range of applications. During CVI a gas flows through a porous body, typically a ceramic fiber preform and, on being heated, it breaks down to yield a solid, the desired ceramic. This is deposited within the pore network and so densifies the composite. It is an intrinsically slow process, however (it can take many hundreds of hours), and therefore the product can be very expensive. Among the different variations developed to overcome these limitations, the use of microwave or radio frequency energy to heat the fiber preform yields the inverse thermal gradient profile mentioned above that causes the preform to be densified from the inside out. This greatly reduces the process times, whilst retaining all of the advantages of the CVI process. SiC_f/SiC composites have been produced using microwave heating in approximately an order of magnitude less time than required conventionally (Porter, 2020), whilst carbon fiber reinforced ZrB_2 - and ZrC -based composites have been prepared in $\sim 40\times$ less time using RF-accelerated CVI (Binner *et al.*, 2020).

Microstructure

Microstructure plays a crucial role in determining the properties of the material and is, in turn, controlled by the quality of the starting powder, which is controlled by the synthesis method, the green forming route and the densification method. The microstructures of structural ceramics and composites can be classified into 6 different categories, these are presented in Fig. 2. Monolithic ceramics are conventionally assumed to have an absence of secondary phases and hence consist of the grains of the ceramic plus any porosity, if present. Additional phases can be added to ceramics in either small or large quantities for one or a combination of reasons; these include enhancing (1) densification, (2) the mechanical, physical or thermal properties, including properties such as the wear resistance, (3) the oxidation and/or ablation resistance and (4) inhibiting the grain growth. The role of secondary phases on densification could be either to enhance the lattice or grain boundary diffusion, or the formation of a liquid phase, see the earlier discussion in the section on Liquid Phase Sintering (LPS). The presence of secondary phases can also enhance the toughness of materials, for example by arresting crack propagation as shown in Table 4; more details of the different toughening mechanisms are provided below in the form of a few case studies on the microstructures of structural ceramics and composites.

Over the past few decades, considerable work has been focused on the production of monolithic ceramics with high strength and toughness. This has examined a number of options, including refining the grain structure (Kingery *et al.*, 1976) and exploiting the opportunities available from zirconia toughening (Wang and Stevens, 1989), particularly from yttria doped zirconia. One option for the latter is yttria stabilized tetragonal zirconia polycrystalline (Y-TZP) ceramics. They are well regarded as strong

Table 4 Typical toughening mechanisms reported in ceramics and its composites

Mechanism	Schematic	Details with examples
Dislocation cloud		Dislocation toughening mechanism usually seen in metals and alloy systems by localised plasticity at the crack tip. In the case of oxide ceramics with predominantly ionic bonding, the dislocations cannot glide on all possible slip planes, involving displacements of ions, in order to maintain the charge neutrality. For non-oxide ceramics with predominantly covalent bonds, dislocation movement is restricted due to directional bonding with an inherent rigid bond network. The dislocation core width of ceramics is narrower than that in metals/alloys, leading to the requirement of high Poirier–Nabarro stress for dislocation glide.
Microcrack cloud		This mechanism can be seen in monolithic ceramics, where the microcracks can act as crack arrestors. The crack tip stress is absorbed by the micro cracks and as a result the primary crack does not propagate further.
Phase transformation		Transition from tetragonal to monoclinic zirconia, in the crack tip stress field involves volume expansion. In a constrained microstructure, this will result in compressive stress on the crack faces, leading to closure of the crack tip. Good examples are given in the sections on Microstructure and Mechanical and Physical Properties.
Crack deflections		Crack deflection is mostly observed in composites containing particulates, whiskers, or fibers as the second phase. Essentially, the crack path is increased as the crack bypasses around the hard or rigid second phase, and the model of Faber and Evans (1983) predicts that the maximum increment in crack deflection induced toughening can be realized in composites with around 30 vol% particulate reinforcement. The particle size, shape and distribution of second-phase particles will influence on the toughness increment.
Grain interlock		This mechanism is similar to the bridging mechanism as explained under whisker and fibre reinforced mechanisms. It is usually observed in the presence of hard second phase particles in metal matrix composites (MMC) such as ODS steels, carbide or boride dispersed Al matrix composites.
Ductile metal second phase bridging		This mechanism is usually observed in liquid metal sintered, cement bonded composites and cermets. In the crack tip stress field, the ductile flow of metallic particles leading to bridging of crack faces reduces the available driving force for crack propagation. The toughness of WC–Co cermets therefore is reduced with lower Co content. From the material-development point of view, a critical amount of Co is required to facilitate liquid phase sintering and the balance of hardness and toughness requires tailoring of the Co content.
Whisker/chopped fibre reinforcement		In whisker-reinforced composites with random whisker alignment, crack bridging also takes place but to a lower extent than fibre toughening. Such bridging also involves whisker pull out and the toughness increment depends on the volume fraction of whiskers.
Continuous fibre reinforcement		This type of toughening is realized in continuous fibre reinforced composites (CMCs). For example, both SiC matrix and SiC fibres are inherently brittle. However, the toughness of SiC/SiC _f composites can be very high and the underlying mechanisms involve crack bridging due to fibre–crack interaction. Such interaction in composites under externally applied tensile stress essentially involves matrix–fibre debonding or matrix micro cracking in the crack wake of the matrix crack or mode I crack, crack deflection at the interface, fibre pull out, and, finally, crack bridging. The combination of these mechanisms essentially results in the nonlinear stress–strain tensile response of the composite, leading to damage-tolerant behaviour. This toughening mechanism is superior to earlier ones; as a result higher toughness could be seen in properly designed CMCs.

candidates for structural applications due to their excellent strength (700–1200 MPa) and reasonable fracture toughness (up to $10 \text{ MPa m}^{1/2}$) in addition to good chemical inertness (Basha *et al.*, 2020). The high toughness of zirconia monoliths comes from the stress induced transformation of the tetragonal (t) phase to the monoclinic (m) phase in the stress field of propagating cracks, a concept that is widely known as transformation toughening, schematically shown in Table 4. Basic microstructural requirements for the effective contribution from transformation toughening is the maximum retention of the tetragonal phase at the application temperature with sufficient transformability to m-ZrO₂ in the stress fields of crack tips. Since the discovery of the concept of transformation toughening in the 1970s, this approach has also been successfully utilized to toughen other ceramic microstructures, for example, extensive efforts have been put into increasing the toughness of alumina by adding zirconia, a class of materials known as zirconia-toughened alumina (ZTA) (Basha *et al.*, 2020).

ZTA and other particle reinforced ceramics, for example SiC_p-reinforced alumina, offer a viable, and relatively cost-effective option, for developing ceramics with improved combinations of mechanical properties, e.g., hardness, strength and toughness. For example, whilst dense alumina with a submicron grain size can be obtained using a fine alumina powder, standard pressureless sintering techniques and relatively low sintering temperatures, the addition of 5 wt% ZrO₂ reduces the mean grain size from 0.5 to 0.7 μm to between 0.4–0.55 μm , whilst still yielding a relative density of 99.0%–99.7% (Abyzov, 2019b). The resulting toughness is described in the next section on “Mechanical and Physical Properties”.

Liquid phase sintered Si₃N₄ ceramic's microstructural features are also very interesting from a toughness perspective (Hampshire, 2008). As indicated previously in the section on LPS, every powder particle of silicon nitride is surrounded by a very thin surface layer of silica. This can react with oxide additives and some of the nitride itself at the sintering temperature to form an oxynitride liquid that promotes densification by solution-precipitation. The equiaxed α -Si₃N₄ dissolves in the liquid and is subsequently precipitated as β -Si₃N₄, which grows in the form of prismatic, hexagonal rod-like crystals that eventually impinge on each other forming an interlocked microstructure, whilst the liquid cools to form an intergranular, usually glass, phase. Well known additives for Si₃N₄ are MgO, Y₂O₃, Al₂O₃ and various rare earth oxides. The amount of additive initially introduced determines the quantity and chemistry of the glass phase and this affects properties such as fracture toughness, ambient and high temperature strengths, creep resistance and oxidation resistance (Hampshire, 2007, 2008). Toughness values as high as 7–10 MPa m^{1/2} have been achieved (Hampshire, 2007).

The highest toughness values for ceramic materials are achieved by reinforcing them with continuous fibers, together with a suitable interface between the matrix and fiber (Tülümen *et al.*, 2019). Continuous fiber CMCs can be made by stacking 2 dimensional (2D) layers, needling the layers to create what are known as 2.5D composites, or by weaving 3D fabrics, performance, and price, increasing in that order. CMCs include carbon fiber/carbon (C_f/C) – though not everyone considers these to be CMCs, C_f/silicon carbide (C_f/SiC), SiC_f/SiC and oxide fiber/oxide (ox_f/ox). More recently, there has been extensive development of ultra-high temperature ceramics and these have also been reinforced, usually with carbon fibers (Sciti *et al.*, 2018). For all fiber-reinforced CMCs, to achieve the required toughness the matrix/reinforcement bond strength must be sufficiently weak to allow relaxation of the stress field at the crack tip and bridging of the matrix cracks by the reinforcement (Parlier *et al.*, 2011). There are 3 approaches, as shown in Fig. 3 (Tülümen *et al.*, 2019). For dense matrix CMCs (e.g., SiC_f/SiC), a low cohesion coating is applied to the fibers before the matrix is formed yielding Weak Interface Composites, WICs, and toughening mechanisms such as crack-deflection, crack-bridging & fiber pullout – though the coating can be vulnerable to oxidation at high temps. The second approach is to form Weak Matrix Composites, WMCs (e.g., ox_f/ox), which have a porous matrix; their reduced stiffness allows

Fig. 3 Reinforcement mechanisms for continuous-fiber ceramic composites. Reproduced from Tülümen, H.M., Hanemann, T., Piotter, V., Stenzel, D., 2019. Investigation of feedstock preparation for injection. Molding of oxide – Oxide ceramic composites. Journal of Manufacturing and Materials Processing 3 (1), 9. <https://www.mdpi.com/2504-4494/3/1/9>.

damage-tolerant behavior but also yields inherent permeability and low strength, wear resistance & thermal conductivity. The third, fugitive coating, approach is less common.

Mechanical and Physical Properties

Ceramics, because of their ionic and/or covalent bonding, have a combination of useful thermo-mechanical properties (high elastic modulus, hardness and strength), excellent corrosion and ablation resistance together with low specific densities. In many structural and tribological applications at room and high temperatures, even in aggressive environments such as irradiation and ablation, ceramics are recognized as having great potential to replace existing materials (Kingery *et al.*, 1976). As implied in the section on Microstructure above, one of the most critical properties, however, is the fracture toughness, which is generally low. A value of around 3–3.5 MPa m^{1/2} is normal for most monolithic advanced ceramics, such as alumina, though as has been shown this can be increased to a value of ~25 MPa m^{1/2} for fiber-reinforced CMCs (Binner *et al.*, 2020).

Toughening mechanisms have been broadly classified into two categories, one involving a process zone around the crack tip, the other related to the bridging of crack faces by reinforcements, which can include particles, whiskers and fibers. The different toughening mechanisms, with associated schematics, are shown in Table 4. The phase transformation mechanism can be seen in the tetragonal phase-stabilized zirconia composites, whilst crack deflection, crack bridging and grain interlock mechanisms are applicable in particulate reinforced composites. Residual grain boundary secondary phases, whether arising from glasses after liquid phase sintering, cements from cementitious bonding or ductile metals from RMI-based processes, can help to bridge cracks, Table 4. Other crack bridging mechanisms also occur in whisker, graphene, chopped fiber and continuous fiber-reinforced composites; the latter also benefit from the fiber pull out mechanism (Binner *et al.*, 2020; Faber, 1997). The latter in particular can contribute to the very high values of toughness (for ceramics) in continuous fiber reinforced composites mentioned in the paragraph above. Important mechanical and physical properties of various structural & thermostructural ceramics are summarized in Table 1, whilst a few case studies are described below.

Addition of 0.3 vol% SWCNTs to Al₂O₃ resulted in retention of alumina's high hardness, 21 GPa, and a fracture toughness of ~5.5 MPa m^{1/2} due to crack bridging and crack deflection mechanisms. The enhanced toughness over monolithic alumina was also explained by the positive effect of an improved matrix/CNT connectivity with the formation of an internal "bamboo" morphology (Akin and Goller, 2015). The electrical conductivity values of the composites were measured as 1050 and 3345 S m⁻¹ for 5.7 and 15 vol% SWCNTs, respectively. These were considered to be very good and were explained by the SWCNTs remaining in contact with each other in the matrix during the SPS densification process, which was performed at relatively low temperature and with a short holding time. The addition of TiB₂ to both Al₂O₃ and B₄C matrices increased their hardness, strength and fracture toughness (Skorokhod and Krstic, 2000). Furthermore, the addition of TiB₂, TiN or TiC can also be used to obtain electro conductive materials, as well as enhanced toughness, when incorporated into Al₂O₃ and Si₃N₄ matrices. These composites can be shaped by electro discharge machining (EDM), allowing the manufacture of complex-shaped components, which has greatly increased the number of industrial applications for these materials (Bilal *et al.*, 2019).

As mentioned earlier, toughening of ceramics by the incorporation of zirconia particulates is well known; in high elastic modulus ceramics such as alumina it is achieved by transformation toughening whilst in elastically softer materials such as zinc oxide the mechanism is based on microcracking – though the latter also reduces the strength (Basha *et al.*, 2020). Values of toughness obtainable with the transformation toughening mechanism, e.g., for ZTA, are typically up to about 10–12 MPa m^{1/2}. This is slightly better than the values for whisker-reinforced composites, e.g., Al₂O₃/SiC_w composites (typically 8–9 MPa m^{1/2}), which are, in turn, better than those for particle-reinforced composites, e.g., Al₂O₃/SiC_p composites (typically 4–6 MPa m^{1/2}) (Abyzov, 2019a). There are also a number of what are effectively "zirconia toughened zirconias", including partially stabilized zirconia (PSZ) and tetragonal zirconia polycrystals (TZPs). There are many reports on them, e.g., (Basu and Balani, 2011), and their toughness values can be as high as 15–25 MPa m^{1/2} for PSZ and 20–30 MPa for TZP (Lin and Duh, 2003), though the precise value obtained is somewhat dependent on the sintering parameters and hence the microstructure. For example, transformation toughness is dependent on grain size and hence the transformability of the tetragonal phase, with the highest toughness being measured at a tetragonal grain size of 1.9 µm (Lin and Duh, 2003). Impurities also play a role on the mechanical properties, for example, 3Y-TZPs sintered using starting powders with a higher impurity content (Daiichi grade; Al₂O₃ 0.72 wt%; SiO₂ 0.08 wt%) exhibited a higher indentation toughness compared with the value for a higher purity ceramic (Tosoh grade; Al₂O₃ <0.005 wt%; SiO₂ 0.007 wt%) (Moradkhani *et al.*, 2019). The quantity of the secondary phase also influences the mechanical properties, for example the fracture toughness of a Y-TZP increased nonlinearly with decreasing yttria content from 2.5 to 2.0 mol %, with a maximum value of 20 MPa m^{1/2} for the 2Y-TZP, although this again will depend on the grain size. An analysis of the effect of yttria content on the properties of nano zirconia has been undertaken (Binner *et al.*, 2011) and it showed that higher yttria content zirconia ceramics also offer some interesting resistance to hydrothermal ageing, albeit at the expense of lower toughness values.

Whilst a 0.5 µm grained B₄C ceramic was reported to have a hardness, flexural strength and fracture toughness of 27 GPa, ~200 MPa and 3.1 MPa m^{1/2} respectively, addition of 3–5 wt% of carbon and TiO₂ played an important role in eliminating the surface oxide layer and also forming the reaction product of TiB₂, thereby resulting in superior mechanical properties such as hardness – 34 GPa, flexural strength – 630 MPa and fracture toughness – 5.1 MPa m^{1/2} (Suri *et al.*, 2010).

Hardness, fracture toughness and flexural strength of refractory borides of TiB₂ and ZrB₂ are reported in the range of 15–25 GPa, 3–6 MPa m^{1/2} and 300–600 MPa respectively. However, the addition of up to 5 vol% Si-based sintering additives (e.g., SiC, Si₃N₄ or silicides) enhances the sintered density of the materials, leading to enhanced mechanical properties of 30 GPa, 6–9 MPa m^{1/2} and 600–800 MPa respectively (Golla *et al.*, 2020).

Thermal Properties

Properties such as thermal conductivity, coefficient of thermal expansion (CTE), and resistance to creep, oxidation, thermal shock and ablation are all important for thermostructural ceramics. Some typical values for selective monolithic ceramics are listed in [Table 1](#), though they are significantly influenced by the presence of porosity and secondary phases. In general, a low CTE and high thermal conductivity are desired for thermostructural ceramics. From [Table 1](#), it is very clear that non-oxide ceramics, especially carbides and borides, have higher thermal conductivities than oxide ceramics and this is a useful property for distributing heat. Hence, the carbides and borides of Zr, Hf and Ta, which also have ultra-high melting points, are under consideration for use in aerospace and other applications where extreme temperature resistance is desired ([Binner et al., 2020](#)). They are also the basis behind the C_f-reinforced UHTCMCs, though it should be noted that continuous fiber reinforced composites usually exhibit anisotropy, especially in their thermal conductivity and CTE.

In general, UHTCs and UHTCMCs need to have a small CTE because a large value can cause instability on the local surface at high temperature as a result of an imbalance in internal thermal stresses. The CTE of the monolithic UHTCs can be affected by the presence of doped secondary phases such as MoSi₂, TaSi₂, ZrSi₂ and SiC. For example, doping with SiC significantly reduced the CTE of HfC and TaC because of the lower CTE of SiC; whilst doping with TaSi₂ or MoSi₂ caused only a minor change in value. Another example is that the addition of 30 vol% SiC to ZrB₂ resulted in a decrease in CTE, however only at higher temperatures (1300–1675K), whilst at lower temperatures (300–1300K) this effect was not observed ([Binner et al., 2020](#)).

Thermal conductivity, κ , is a strong function of temperature and secondary phases. For example, the incorporation of CNTs to ceramics enhances their thermal conductivities since the value for individual MWCNTs and SWCNTs are 3000 Wm⁻¹ K⁻¹ and 6000 Wm⁻¹ K⁻¹ respectively at room temperature ([Akin and Goller, 2015](#)). Addition of MoSi₂ into ZrB₂ leads to a decrease in thermal conductivity, whilst 5–30 vol% SiC increases it ([Binner et al., 2020](#)). On the other hand, increasing temperature causes the thermal conductivity of borides to decrease whilst that of carbides increases ([Golla et al., 2020](#)).

Creep and thermal shock resistance are also important high temperature properties for structural applications. Whilst monolithic ceramics generally have good creep resistance due to their high melting points, especially for non-oxide ceramics, the presence of secondary phases, particularly glassy phases such as those that can remain after liquid phase sintering, can decrease the creep resistance. For example, commercially produced Al₂O₃ powders typically contain impurities such as silica, calcia, magnesia, soda and potassium oxide. These form liquids during sintering that can promote the formation of a more dense ceramic, but reduce the high temperature mechanical properties, including strength, creep and thermal shock resistance, by forming glassy grain boundary phases ([Abyzov, 2019a](#)). Similar results can be found for liquid phase sintered silicon nitride-based ceramics (β -SiAlON); however by carrying out a post-sintering heat treatment at ~1350°C the creep resistance can be improved. The heat treatment allows the matrix and grain-boundary glass phase to react to yield a slightly modified β -composition and a crystalline yttrium aluminum garnet, Y₃Al₅O₁₂ phase ([Hampshire, 2008](#)). This material has excellent creep resistance and is the strongest SiAlON ceramic compared to Si₃N₄. Creep behavior is also dependent on both intergranular film and triple point viscosities and hence doping larger RE cations into silicon nitride or SiAlON can enhance the creep resistance by enhancing the viscosity of these liquid films at elevated temperatures ([Hampshire, 2008](#)).

In many applications ceramics are exposed to thermomechanical stresses because of transient thermal conditions such as a sudden change in temperature, for example in a high temperature furnace or a gas turbine engine ([Singh and Wang, 1995](#)). When a material is subjected to a thermal transient of suddenly decreasing temperature (ΔT), e.g., in a quench test, the surface of the material is placed under a tensile stress and the interior under a compressive stress. Under these conditions, ceramics are susceptible to catastrophic failure, known as thermal shock, because of their brittleness, relatively low thermal conductivity and high Young's modulus of elasticity. A number of thermal shock resistance parameters, denoted R, have been developed that indicate the maximum allowable temperature difference to which a body can be subjected without the initiation of fracture under a range of different thermal conditions ([Li et al., 2014](#)). The most common version of R is that shown below, which represents the maximum allowable heat flux a body can take before fracture initiates under steady heat flow conditions, or the maximum allowable temperature difference to which a body can be subjected without the initiation of fracture under mild transient thermal shock conditions ([Kingery et al., 1976](#)):

$$\Delta T_c = \frac{\sigma_t(1 - \nu)}{\alpha E} = R$$

where σ_t is the tensile strength, ν Poisson's ratio, α coefficient of thermal expansion, E Young's modulus. The R values presented in [Table 1](#) are calculated using the above equation. The change in the coefficient of thermal expansion (α) has the most profound effect, whilst a change in the thermal conductivity (κ) has a relatively smaller influence ([Singh and Wang, 1995](#)).

Continuous fiber reinforced ceramic matrix composites (CMCs) possess superior resistance to thermal shock damage than monolithic ceramics; however matrix cracking can still be induced by thermomechanical stresses produced during thermal shock, leading to the onset of damage, which, in turn, can decrease the strength and elastic modulus of the composite ([Arai et al., 2019](#)). These matrix cracks can grow during cyclic thermal shock loading ([Singh and Wang, 1995](#)). The extent of the damage is limited by the presence of the continuous reinforcing fibers, which generally means that the catastrophic failure typical of a monolithic ceramic is avoided, although the extent of the thermal shock resistance is dependent on several factors including the strength of the fiber-matrix interface. Too strong or too weak an interface means that the extent of damage protection is reduced, so a weakly-bonded interface is required to achieve the required crack deflection and crack bridging ([Singh and Wang, 1995](#)). It follows that

Fig. 4 Typical Oxyacetylene (OAT)/oxypropylene torch (OPT) test facility at University of Birmingham (1) Back face thermocouple, (2) water cooling, (3) sample holder, (4) sample, (5) sample guide, (6) protective insulation, (7) oxyacetylene torch, (8) neutral density filter, (9) thermal imaging camera and (10) 2 color pyrometer. any process that affects these mechanisms, such as degradation of the fiber-matrix interfacial properties, e.g., through oxidation, will also degrade the thermal shock resistance of the CMCs (Singh and Wang, 1995).

Whilst mentioning the oxidation resistance of thermostructural ceramics and their composites, it can be significantly enhanced by appropriate compositional design so that it leads to the formation of a surface layer of immiscible, multicomponent glass (Murthy, 2020b). The resulting increased liquidus temperatures and viscosities, as well as decreased oxygen diffusivities in the immiscible glasses, are considered responsible for the observed improvement in the oxidation resistance of the composites. It is therefore beneficial to optimize the type and quantity of glass-forming elements present in the ceramics, typically by incorporation of appropriate additives. However, in doing so, it is important to balance the resulting enhanced oxidation resistance with the material's other properties, including mechanical, physical and thermal, to best suit the particular application. As has already been shown, the incorporation of glassy secondary phases can reduce high temperature properties such as strength and creep resistance.

Over the past decade, researchers around the world have investigated the oxidation behavior of a range of thermostructural ceramics, including TiB_2 , CrB_2 , ZrB_2 , HfB_2 , SiC , ZrC , HfC and TaC amongst others (Binner *et al.*, 2020; Sonber *et al.*, 2014). Modification of the chemical composition of the oxide surface layer, leading to a decreased inward diffusion of oxygen, is one of the ways of controlling the oxidation resistance of non-oxide ceramics. This modification can be accomplished by either changing the bulk composition or by applying suitable coatings. The addition of silica formers or rare earth elements, notably silicides, SiC , Si_3N_4 , Ti_3SiC_2 , Y, La, Eu, Ce and Yb, can reduce the oxidation rate through the formation of a more stable borosilicate glass/rare earth (RE) oxide up to $\sim 1600^\circ\text{C}$ (for Si formers) and $> 2000^\circ\text{C}$ (for RE oxides). Several groups have studied the effects of SiC additions on the behavior of borides or carbides when exposed to air at elevated temperatures (Fahrenholtz *et al.*, 2007). It is known that borate and silicate glasses containing transition/rare earth oxides show a strong tendency to phase separate as a result of immiscibility in the phase diagram. Systems exhibiting such immiscibility are characterized by steeply rising liquidus temperatures and increased viscosity. As demonstrated by the Stokes-Einstein relationship (Murthy, 2020b), the latter decreases the oxygen diffusion rate through the oxide surface scale, since the diffusivity is inversely proportional to viscosity. Another potential benefit of increased viscosity, as well as increased liquidus temperature, is the suppression of boria/silica evaporation from the glass (Binner *et al.*, 2020).

With the increasing interest in ultra-high temperature ceramics and composites, materials that withstand temperatures up to and indeed above 3000°C , for aerospace applications such as hypersonic vehicles, testing the oxidation/ablation resistance using oxyacetylene torches (OAT) and oxypropylene torches (OPT) is increasing. OAT testing can reach temperatures up to $\sim 3000^\circ\text{C}$ and heat fluxes up to $\sim 17 \text{ MW m}^{-2}$, whilst the equivalent figures for the OPT test are $\sim 2500^\circ\text{C}$ and $\sim 6 \text{ MW m}^{-2}$ (Binner *et al.*, 2020). A typical OAT/OPT test schematic is shown in Fig. 4 and a video clip of a typical test can be found *here*. Interestingly, the gas velocity for both systems, which has been directly measured, were very similar at Mach ~ 0.6 . The flames involved can also be manipulated by varying the gas chemistry to be oxidizing, reducing or neutral and the distance between the flame and the sample and the angle the flame makes on contact with the sample can all be varied (Binner *et al.*, 2020). As an aside, it is interesting to note that the rapid oxidation of borides and carbides at $\sim 600^\circ\text{C}$ results in the formation of B_2O_3 or CO/CO_2 respectively. Whilst the latter are gases and hence are evolved immediately, the former melts first and only evaporates at $\sim 1000^\circ\text{C}$. This is believed to explain the result that ZrB_2 and HfB_2 both develop a more protective oxide coating than ZrC or HfC ; the oxide scale on the latter has a strong tendency to spall off whilst that on the borides typically remains attached (Binner *et al.*, 2020).

Summary and Outlook

The interest in structural/thermostructural ceramics and their composites arise due to their combination of high hardness, strength (including high temperature and creep strength), elastic modulus and wear resistance, together with good thermal shock, corrosion and ablation resistance and a relatively low specific gravity. Toughness is also relatively high in the composites, though it is

generally much lower in the monolithic ceramics. Whilst there are many applications for these materials in a wide variety of environments, including wear, erosion, corrosion, ablation, high temperatures and irradiation, amongst others and including combinations of all of them, further applications are often limited by their relatively high costs compared to other types of materials (Binner *et al.*, 2020; Murthy, 2012). The latter arise due to the complexity of the processing required, usually combined with the need to use high temperatures and, for the non-oxide ceramics, controlled atmospheres. Ongoing research and development is contributing to both the formation of materials with enhanced properties and the creation of lower cost processing and hence the range of applications for these ceramics is increasing.

Whilst oxide ceramics are generally obtained from minerals using what essentially amount to purification processes, non-oxide ceramics need to be synthesized from synthetic precursors in controlled atmospheres at high temperatures due to their high melting points and low self-diffusivity coefficient (Abyzov, 2019a). Both types of ceramic are fabricated, however, using similar green forming routes and subsequent densification by sintering. For oxides, however, the latter is generally done pressureless, whilst non-oxides need elevated pressure, typically involving hot pressing, hot isostatic pressing or, more recently, spark plasma sintering. This makes the densification of the non-oxides much more expensive. A major world-wide research effort is focused on both reducing the fundamental costs associated with manufacturing these materials as well as trying to improve the energy efficiency to make the processes more sustainable.

Oxide ceramics have generally good chemical and corrosion resistance, including towards molten metals, and, therefore, find many applications as containment materials, e.g. crucibles, tubes and refractories for molten metals, glass and high temperature furnaces. Oxides, particularly alumina, also display good erosion and wear resistance so they are also used as coatings for wear tiles, liners and grinding media. Alumina also has the advantage that its precursor material, bauxite, is relatively abundant, which helps to keep the ceramic relatively cheap. Non-oxide ceramics generally display high thermal conductivities, low thermal expansion coefficients combined with high hardnesses, melting points and stiffnesses. Whilst they have been explored for high temperature applications for several decades, very recently, the borides and carbides have also been extensively explored in terms of their potential for ultra-high temperature applications, including rocket nozzles and leading edges. The borides and carbides are also considered for a range of nuclear reactor applications (Krenkel *et al.*, 2006). The neutron absorption cross section should be low for reactor structural components and high for shielding, control/safety rod applications. Borides and B_4C are the potential neutron absorbers; hence these materials are widely used for control rod applications in commercial nuclear power reactors. ZrC and WC are the choice for first wall materials in fusion reactors. With lower cost manufacture, ideally with further enhanced properties, the number of applications for all these ceramics could increase significantly.

It is a well-known fact, however, that all monolithic ceramics, not just the structural and thermostructural ceramics, suffer from poor fracture toughness. Values in the range 3–6 MPa m^{1/2} are common; these are at least an order of magnitude lower than even relatively poor toughness metals. The addition of a secondary phase in the form of ceramic or metal particulates, whiskers (though these are not permitted everywhere in the world) or chopped fibers can all lead to higher toughness values, particularly for zirconia-based ceramics. However, the greatest increases in toughness arise when continuous fiber reinforcement is used. The latter ceramic matrix composites (CMCs) are a rapidly evolving and growing technical field with a very wide range of applications across the aerospace, defense, energy, medical and transport sectors as a result of their superior mechanical and physical properties. Continuous fiber CMCs combine the advantages of the high temperature properties of the matrix phase with a high flaw tolerance (Binner *et al.*, 2020). As a result, these composites offer pseudo-ductility behavior due to a range of mechanisms, though implicit in these mechanisms is the assumption that the matrix cracks are bridged to some degree by the fibers. Historically, the use of pressure-based sintering routes to create CMCs has typically resulted in coarse microstructures and damage to the continuous fibers due to the high sintering temperatures required. Without the use of an appropriate interfacial layer, the components are brittle. However, the high density achieved yields good strengths and reduces the risk of oxidative attack of the fibers (and matrix). Other methods such as precursor impregnation and pyrolysis (PIP), reactive melt infiltration (RMI) and chemical vapor infiltration (CVI) are also commonly used techniques for fabricating CMCs (Binner *et al.*, 2020), though each has their own advantages and disadvantages. Very recently, research into ultra-high temperature ceramic matrix composites (UHTCMCs) has led to materials that have potential for applications in aerospace (e.g. rocket nozzles and leading edges), high temperature nuclear fission and fusion reactors as well as concentrated solar power receiver materials.

Introduction

Alumina materials are a family of ceramics whose principal constituent is α -aluminum oxide (α -Al₂O₃), known as alumina in the ceramic sector. On a weight basis, these materials have the largest share of the ceramics world market.

Alumina is the ceramic material most extensively studied both from theoretical and practical stand points. There exist several reviews about alumina materials – properties, production and uses – (Gitzen, 1970; Dörre and Hübner, 1984; Kingery, 1984; Hart, 1990; Briggs, 2007; Doremus, 2008; Riley, 2009), on which this chapter relies to summarize the basic aspects of alumina materials. It adds to the previous publications by dealing with new developments and trends that were just proposed as possibilities in some of these reviews. More recently, processing and processing-related properties of alumina materials have been reviewed (Baudín, 2014a) and new and future applications were extensively analyzed in a comprehensive book dealing with the engineering of alumina ceramics (Ruy, 2019).

Etymology of the name alumina comes from the mineral alum (KAl(SO₄)₂ · 12H₂O), used since the years 3000 BCE in medicine, alchemy, and industry. First patents on commercial applications of single-phase alumina date from the beginning of the 20th century. For instance, an early German patent describes the production of alumina dies for drawing wires (General Electric Company, 1913) and the first British Patent (Thomson-Houston Company, 1913) deals with components for wear-resistant applications such as tools, bearings, dies, and drills.

Widespread commercial applications of alumina came later, in the 1930s, when alumina started to be used for various applications such as crucibles for corrosive liquids, cutting tools for metal machining and high voltage electrical insulators. The requirements of increasing temperatures of the combustion aeroengines during the period preceding World War II led to the need for electrical insulators capable of withstanding higher temperatures. The first large scale use was in spark plug insulators, constituted by 90–95 wt% aluminum oxide and glass formed by liquid-phase sintering aids.

The widespread usefulness of alumina is due to a variety of properties such as high melting point (2054°C), high chemical stability in different environments, hardness, strength, abrasion resistance, electrical resistance and transparency. A huge research effort was dedicated to alumina since the 1950s, leading to numerous new applications of advanced materials in technologies that were emerging during the last quarter of the 20th century.

Alumina materials present a wide range of compositions from nearly 100% aluminum oxide with trace elements used as sintering additives or associated impurities to materials containing up to 20 wt% of other constituents. In most cases, aluminosilicates are present in the materials as glass. Materials with amounts of glass up to 10 wt% are considered as alumina ceramics while those with larger amounts are included in the group of alumina porcelains.

The microstructures of advanced alumina materials consist of small, normally ≤ 30 μ m, aluminum oxide grains strongly bonded across grain boundaries. Small amounts of glass might be present in the form of very thin films at the grain boundaries (1–2 nm). Those ceramics containing aluminosilicates usually have glass forming pockets at triple points and grain boundaries. Commercial aluminas for more highly demanding applications such as hip joints for arthroplasty or cutting tools have typical grain sizes under 5 μ m.

In **Table 1**, the main commercial applications of alumina materials and the properties required for the envisaged application are summarized.

As a single-crystal, alumina is prized as gemstones (sapphire or ruby, depending on the impurities) and for special applications such as watch bearings. Moreover, some high grade glass substitutes are made of single-crystal alumina (artificial sapphire). In coarse polycrystalline form, alumina is the major constituent of high grade shaped and unshaped refractory materials. In the form of powder and grids, alumina is used as grinding and abrasive media. In the form of whiskers and fibers, alumina is used for low-thermal-mass furnace insulation and metal reinforcement. Porous sintered aluminas are used as catalyst supports for chemical processes. Alumina-based materials with different alumina contents (from around 88 to more than 99.5 wt%) and micrometer grain sizes are used for a wide range of applications requiring specific mechanical, chemical, electrical, optical and biomedical characteristics.

Structural applications of alumina at room temperature are based on the combination of hardness, wear resistance, and corrosion resistance that alumina provides. Room temperature applications include wear parts in medical engineering (prostheses for hip and knee joints), in process plants (pump components and valve faces, lining of pipework), and in mechanical engineering (bearings and valves). Alumina pieces of different shapes and sizes are currently used as textile guides.

Alumina presents also high refractoriness; that is, high melting point and retention of structural integrity at high temperature. Due to its high refractoriness, one of the most successful applications of alumina is in cutting tools for high speed machining of metals, which have experienced a huge development since their commercial introduction in the early 1950s.

Applications of alumina in components for engines are limited by its low thermal shock resistance as compared to that of non-oxide ceramics.

Table 1 Commercial applications of alumina materials and the related properties

	<i>Applications</i>	<i>Primary property</i>	<i>Other properties</i>
Single crystal	Gemstones	Esthetics	Mechanical stability at room temperature
	Glass substitutes	Translucency/Transparency	Hardness and stiffness up to 1000°C
	Special applications (e.g., watch bearings)	Hardness and stiffness	
Grains	Abrasives	Hardness	
	Aggregates for unshaped refractories		
Shaped: Polycrystalline	Shaped refractories	Chemical inertness at high temperature	Hardness and stiffness at high temperature
	Catalyst supports for chemical processes	Porosity and chemical inertness	Dimensional stability
	Mechanical engineering (e.g., bearings and valves)	Wear resistance at room temperature	Chemical inertness at room temperature
	Process plants (pumps, valves, pipeworks...)		
	Cutting tools for metals	Wear resistance up to 1200°C	Hardness and stiffness at high temperature
			Chemical inertness
	Wear resistant parts (mining, textile, paper, food ...)	Wear resistance	
	Medical engineering (e.g., total prostheses for hip joints)	Biocompatibility	Wear resistance at room temperature
	Feedthroughs for bionic implants	Biocompatibility and bioinertness	Stiffness and strength
		High electrical resistivity	
	High voltage spark plug insulators (> 80 to 95% alumina)	Electrical resistivity at high temperature	Strength
			Chemical inertness
	Substrates for semiconductor and microelectronics industry	Electrical resistivity	Dimensional stability
			Low loss tangent (High frequency applications)
	Armor	Resistance to impact	
	Glass substitutes	Translucency/Transparency	Hardness and stiffness up to 1000°C

The optical properties of alumina together with its structural stability make it an ideal substitute for glass in harsh environments.

As reported by [Ruy \(2019\)](#), from an economic point of view, the most significant applications for alumina are as substrates in the semiconductor and microelectronics industry and in medicine. Alumina is one of the most satisfactory materials for bearings for arthroplasty due to its biocompatibility and its high wear resistance. The high electrical resistivity together with biocompatibility and bioinertness and dimensional stability makes alumina the ideal material for feedthroughs in bionic implants, which has meant a true revolution in the sector of implantable bionics.

Apart from the specific properties of alumina, there are two factors that contribute to the wide use of alumina ceramics for advanced applications: the availability of raw materials and the possibility of sintering high purity alumina ceramics to full density.

The attractive technological properties of alumina ceramics are due to the properties of their main component, α -Al₂O₃, which are determined by its crystalline structure and the nature of the bonds.

This chapter deals with high purity (>95 wt%) and fine grain size ($\leq 30 \mu\text{m}$) wear resistant alumina ceramics, thus, alumina porcelains, and refractories will not be addressed. Zirconia toughened alumina (ZTA) will also be considered when discussing alumina as a biomaterial. First, the thermodynamics of Al₂O₃ will be analyzed. Then, the crystalline structure and the related properties of single-crystal α -Al₂O₃ will be discussed. Then, the main processes for the production of alumina materials with controlled microstructure will be summarized. The properties and applications of alumina materials will then be discussed in relation to those of single-crystal α -Al₂O₃ and microstructure. Last, the most recent and future applications of alumina materials will be summarized.

Thermodynamic Stability

As stated by [Brewer \(1953\)](#) in his exhaustive review, from a thermodynamic stand point, α -Al₂O₃ is one of the most stable of the metal oxides. This fact is clearly demonstrated by the large negative Gibbs energy of formation from the metal, ΔG_T , according to:

Where ΔG_T values range from -1590 to -945 kJ/mol from $T = 273\text{K}$ to $T = 2273\text{K}$ (calculations using the program Outokumpu 1993). This high thermodynamic stability is responsible for the absence of natural deposits of free Al.

Dissociation of Al_2O_3 to two sub-oxides, Al_2O and AlO , has been reported to take place at high temperature and low oxygen partial pressures (Brewer, 1953; Brewer and Searcy, 1951) according to:

However, even though both reactions present a negative Gibbs energy, the corresponding equilibrium constants are extremely low, e.g., at 1773K, $K = 2.76 \times 10^{-30}$ and 4.56×10^{-24} for reactions (2) and (3), respectively, (calculations using the program Outokumpu 1993). Therefore, alumina experiences extremely low weight losses in vacuum, even at high temperatures, e.g., $\approx 10^{-6}$ – 10^{-5} kg/m²·s in the temperature interval 1973–2273K (Harper, 2001).

Even though the fusion temperature of alumina is very high, liquids can be formed at the lower temperatures of the invariant points associated with impurities. Some examples of liquid forming temperatures (Levin *et al.*, 1964) are those corresponding to the systems Al_2O_3 – SiO_2 (1590°C: mullite-tridymite), Al_2O_3 – SiO_2 – CaO (1170°C: pseudowollastonite-tridymite-anorthite), Al_2O_3 – MgO – SiO_2 (1355°C: protoenstatite-cordierite-tridymite), Al_2O_3 – SiO_2 – K_2O (689°C: quartz-potash feldspar – $\text{K}_2\text{Si}_4\text{O}_9$, 990°C: leucite-mullite-cristobalite) and Al_2O_3 – SiO_2 – Na_2O (720°C: quartz-albite-anorthite). Some of these impurities can be used as sintering aids to increase the final density and/or reduce the sintering temperature of polycrystalline alumina materials. However, they remain at the grain boundaries in the sintered material, most often in glass form, and are detrimental for the high temperature structural integrity of the materials. In the same way, the chemical inertness of α - Al_2O_3 makes materials with above 99% alumina resistant to chemical corrosion by liquids – acidic, caustic, and saline – while silicate impurities dramatically reduce corrosion resistance.

Single-Crystal Aluminum Oxide

Crystalline Structure

The main constituent of alumina ceramics is α - Al_2O_3 , which is the only crystalline form of pure aluminum oxide at ambient pressure throughout the whole temperature range up to the melting point (2054°C). It is important to remark that β -alumina and γ -alumina are not different polymorphs of Al_2O_3 , as such confusing nomenclature would suggest. β -alumina is sodium aluminum oxide of composition $\text{Na}_2\text{O} \cdot x\text{Al}_2\text{O}_3$ ($x = 5$ –12) while γ -alumina powders are poorly crystallized hydrated aluminum oxide powders. The crystalline phase α - Al_2O_3 is called corundum and, in the single-crystal form, corundum is called sapphire.

The crystalline structure of α - Al_2O_3 – hexagonal structure, D_{3h}^6 space group – is described in several sources (e.g., Deer *et al.*, 1992; Brook, 1991); (See Relevant Websites section).

This crystal lattice can be described by planes of hexagonal close packed oxygen ions (Fig. 1(a)) that leave octahedrally coordinated sites which are occupied by Al^{3+} ions. The radius of the O^{2-} ion (140 pm) is larger than that of Al^{3+} (50 pm). Only two thirds of the sites are filled by Al^{3+} ions due to the 2:3 at. proportions in Al_2O_3 (Fig. 1(b) and (c)). Thus, the Al^{3+} ions are

Fig. 1 Crystalline structure of sapphire. Gray: oxygen atoms; blue: aluminum atoms. (a) Planes of hexagonal close packed oxygen ions. (b) Ideal structure showing the atom distribution. (c) Ideal structure showing the atom distribution and the O–Al bonds.

bonded to 6 oxygen forming AlO_6 octahedrons. Each such octahedron shares a face with one on the upper and one on the lower layers. The real structure is not symmetrical as polarization is produced when the small cations with large charges occupy the interstices. Then, three O^{2-} are closer to each Al^{3+} than the other three and the octahedrons are distorted, the mean aluminum-oxygen distance being 192 pm. The measured *a* and *c* lattice parameters are 476 pm and 1299 pm, respectively, giving a theoretical density for the single-crystal of 3990 kg m^{-3} (Powder X Ray diffraction file ASTM42-1468).

Aluminum oxide is considered to be ionic, constituted by Al^{3+} and O^{2-} ions; however, its bonds have some covalent character (Sousa *et al.*, 1993). As the share of ionic character to the bond is 63%, there is a highly covalent contribution to the bond strength, which is high.

As with all non-cubic materials, aluminum oxide presents anisotropy in properties at the crystalline level which is higher in ionic oxides due to partial polarization. Properties of sapphire are determined by the close packed and anisotropic crystalline structure and the high energy bonding, as discussed below.

Elastic and Mechanical Properties

The most direct measurements of the bond strength of single-crystals are the elastic constants. Values of the single-crystal compliances (*C_{ij}*) and stiffnesses (*S_{ij}*) determined by different authors were collected by Bradt and Scott (1990) who found that values determined by different authors from 1960 were coincident. Anisotropy in Young's modulus for sapphire is lower than for other oxides. The difference between the values of Young's modulus in directions parallel (430 GPa) and perpendicular (465 GPa) to the *c* axis is small and a minimum value occurs in an intermediate direction (380 GPa). As shown in Fig. 2, this small anisotropy in Young's modulus is maintained at high temperature, where a minimal decrease occurs from room temperature up to 1000°C. The decrease of stiffness with temperature is due to the increase in atomic displacements originated by atomic vibrations and the associated reduction in bond strength.

In addition to the high Young's modulus, the high bond strength in the close-packed crystal structure of $\alpha\text{-Al}_2\text{O}_3$ is reflected in the fact that sapphire is one of the hardest materials, with a hardness of 9 on the Mohs scale (non-linear, 1: talc, 10: diamond) and Vickers hardness up to 30 GPa, depending on the orientation (Ryshkewitch and Richerson, 1985).

In terms of comparison, only some non oxide ceramics present higher Young's modulus, *E*, and hardness, *H*, values than $\alpha\text{-Al}_2\text{O}_3$. For instance, values of $H = 61 \pm 1 \text{ GPa}$ and $E = 1070 \pm 30 \text{ GPa}$ have been determined by nanoindentation on the (111) plane of single-crystals of cubic BN (Deura *et al.*, 2018). In the case of SiC, which is considered a hard material, values of Knoop microindentation (100 g) hardness between 22 and 30 GPa for $\alpha\text{-SiC}$ (Shaffer, 1964) and between 27 and 30 GPa for $\beta\text{-SiC}$ (Shaffer, 1964), depending on orientation, have been reported.

Sapphire can experience plastic deformation depending on the temperature and the stress history (Jones and Tressler, 1991).

Deformation of sapphire fibers is linear up to temperatures above 1600°C for most orientations. For instance, sapphire fibers oriented such that the basal (0001) plane is perpendicular to the fiber axis possess high deformation resistance due to the extreme anisotropy of the sapphire crystal structure, resulting in few slip systems available to be activated. Also, the high covalent contribution to the alumina bond strength further increases the Peierls force needed to initiate slip.

Dislocation glide in sapphire occurs at high temperature (Bradt and Scott, 1990). Basal slip on the close-packed oxygen planes is the most common. Below 1600°C, plastic flow occurs by slip on the basal plane (0001) in the $[\bar{1}\bar{1}20]$ direction both in tension and compression in the temperature range of 900–2000°C, depending on the applied stress, as first identified by Watchman and Maxwell (1957). The second most common slip system is on the prism plane ($\bar{1}2\bar{1}0$) in the $[\bar{1}010]$ direction.

Fig. 2 Young's modulus of $\alpha\text{-Al}_2\text{O}_3$ as a function of temperature. Data for a dense (>99% of T.D.) alumina material and for single-crystal in the indicated crystalline planes, (0001) and ($\bar{1}2\bar{1}0$). Plotted from Gitzen, W.H., 1970. Alumina as a ceramic material American Ceramic Society Special Publication No. 4. Ohio, USA: The American Ceramic Society. Bradt, R.C., Scott, W.D., 1990. Mechanical properties of alumina In: Hart, L.D. (Ed.), Alumina Chemicals Science and Technology Handbook. USA: The American Ceramic Society Inc, pp. 23–39.

The fracture behavior of alumina single-crystals has been extensively studied over many years because of its technological interest in the crushing of single-crystal grains of alumina abrasives and the fabrication of jewelry. Crack propagation in sapphire occurs as cleavage on specific crystallographic planes, being the rhombohedral R plane ($\bar{1}012$), the one which cleaves more easily at room temperature and the basal plane (0001) the most difficult to cleave (Bradt and Scott, 1990). Wiederhorn and colleagues (Wiederhorn, 1969; Wiederhorn *et al.*, 1973) measured a surface energy of 6 Jm^{-2} for the former one and estimated that of the later one to be higher than 40 Jm^{-2} . Iwasa and Bradt (1984) reported K_{IC} values of 2.4 ± 0.1 and $4.5 \pm 0.3 \text{ MPam}^{1/2}$ for ($\bar{1}012$) and (0001), respectively. The easiness of cleavage of plane ($\bar{1}012$) is due to the large array of vacant cation lattice sites parallel to this plane. Wiederhorn attributed the high resistance of the basal plane to cleavage to a lack of charge neutrality in this plane.

Iwasa and Bradt (1984) studied the effect of temperature on K_{IC} of different crystallographic planes, from room temperature up to 1400°C . The temperature increase affected differently the different planes. The plane for which the effect was more severe was (0001) for which K_{IC} at 800°C was about one quarter of the value at room temperature and increased for higher temperatures revealing plastic deformation. This phenomenon was also detected for the plane ($10\bar{1}2$).

Sapphire presents relatively high strengths that are lower than its theoretical strength, calculated using the simplest relationship ($\sigma_t \approx 0.1 \cdot E = 38\text{--}46 \text{ GPa}$). Room temperature bending strengths of $400\text{--}700 \text{ MPa}$ and tensile strengths of 500 MPa , depending on orientation and surface imperfections, are common (Brook, 1991; Riley, 2009). Moreover, values up to 7 GPa have been reported for flame polished artificial sapphire rods (Brook, 1991; Watchman and Maxwell, 1959) which are increased up to 11 GPa for thin filaments. Recent data for microcantilever beams ($10\text{--}30 \mu\text{m}$ long, width and depth $2\text{--}5 \mu\text{m}$), machined by FIB and tested in a nanoindenter, range from 10 to 13 GPa for monocrystals.

In agreement with the variations of Young's modulus and K_{IC} , classical works on tensile properties of sapphire filaments reported changes of strength with temperature. Reported strength values for sapphire filaments grown in the direction of the c axis follow non-monotonous dependence on temperature (Shahinian, 1971). A significant decrease from room temperature down to around 500°C was attributed to brittle fracture while an increase from this temperature up to 1000°C was explained by microplastic deformation at stress concentrations. Bayer and Cooper (1969) measured the tensile strength of sapphire filaments of diverse origins and orientations and found a decrease of strength from room temperature up to 1000°C that could be associated with brittle fracture. From around 1200°C , strength experienced a slight increase in agreement with the occurrence of plastic deformation processes. More recently, flexural strength determination in sapphire for high temperature pressure sensors showed a decrease of about 6% for every increase of 100°C from 750 MPa at room temperature to 350 MPa at 1200°C (Guo *et al.*, 2018).

Thermal and Functional Properties

Thermal and functional properties of single-crystal $\alpha\text{-Al}_2\text{O}_3$ present slight anisotropy due to the anisotropy of the crystal structure.

$\alpha\text{-Al}_2\text{O}_3$ exhibits a relatively low crystalline average thermal expansion coefficient, $\alpha \approx 8.7 \times 10^{-6} \text{ K}^{-1}$ between 25 and 1000°C (Taylor, 1984). However, there is a perceptible larger thermal expansion coefficient parallel to, rather than perpendicular to, the c axis, $\alpha \approx 9.2$ and $8.4 \times 10^{-6} \text{ K}^{-1}$ between $25\text{--}1000^\circ\text{C}$, in the parallel and perpendicular directions, respectively (Taylor, 1984). This thermal expansion anisotropy is responsible for the development of stresses in polycrystalline alumina materials when cooling from the sintering temperature. As will be discussed, manipulation of microstructure in order to control the effect of the thermal stresses is the main way for optimizing the fracture behavior of alumina materials.

In nonmetallic solids, heat is transported by phonons (i.e., lattice vibrations). Thermal conductivity is determined by the mean free path of phonons which, in turn, is dependent on temperature, phonon-phonon interactions and scattering by lattice defects. Reported values of thermal conductivity of sapphire are highly dependent on the fabrication method because of the strong effect of defects, in particular, those derived from impurities. Also this property is slightly anisotropic, being higher in the direction parallel to the c axis than in the direction perpendicular, e.g., (See Relevant Websites section) for commercial optical sapphire at room temperature $K = 25.8$ and 23.0 W/mK in directions parallel and perpendicular, respectively. Values of average thermal conductivity of sapphire as a function of temperature have been summarized and discussed by Doremus (2008) and are plotted in Fig. 3. At very low temperatures ($\leq 40 \text{ K}$) the mean free path of phonons is determined by specimen dimensions because scattering occurs from the specimen surfaces, and the thermal conductivity is very high. From 40 K , conductivity decreases sharply due to the increase of phonon-phonon interactions. Above 1073 K (800°C), the mean free path is of the order of lattice distances and it becomes constant with temperature. Thermal conductivity of around 40 W/mK at room temperature makes sapphire a relatively good thermal conductor.

The electrical properties of sapphire were extensively reviewed and analyzed by Gitzen (1970) and, more recently, by Doremus (2008). Values of the electrical properties of sapphire are shown in Table 2. The electrical resistivity is one of the highest of all known materials while the dielectric loss tangent is among the lowest.

Sapphire is well known as an optical material because of its excellent transmittance. Sapphire, together with Mg-Al spinel and aluminum oxynitride (ALON®) transmit from about $5 \mu\text{m}$ in the infrared to at least as far as $\approx 0.2 \mu\text{m}$ in the ultraviolet. As sapphire is mechanically stronger, thinner sapphire windows, with the associated increase in transmittance, are required. As in the case of other properties analyzed in this chapter, sapphire presents anisotropy in the refractive index. Comprehensive data on the optical properties of sapphire can be found in the classical book by Gitzen (1970). Synthetic sapphire windows are used in both high pressure and vacuum chambers for spectroscopy, watch faces, barcode scanners due to its resistance to scratching. Due to the high temperature stability it is also used in windows of laser tubes and, to a lesser extent, small dimension tubes ($1\text{--}10 \text{ cm}$) of sapphire are used as vapor-tight envelopes in sodium vapor lamps due to its excellent corrosion resistance.

Properties – Summary

From a thermodynamic stand point, α -Al₂O₃ is one of the most stable of the metal oxides and its melting point is high.

Single-crystal α -Al₂O₃ presents very interesting mechanical properties such as high stiffness and hardness which are maintained at relatively high temperatures but it lacks toughness. It has a relatively high thermal conductivity for an oxide. From the stand point of electrical properties, it is an excellent insulator because of its high resistivity and low dielectric loss. Also sapphire has excellent optical transparency.

Most of the work on the development of alumina materials has been devoted to take advantage of the desired properties of the single-crystals by controlling the microstructure. High purity aluminas with controlled grain sizes have been developed for advanced applications in different fields as will be discussed in the following sections. In particular, the thermal expansion anisotropy has been used as the basis for toughness increases.

Production of Alumina

Aluminum is the third most common element in the Earth's crust (≈ 8 wt%), after oxygen and silicon, with enough economically available reserves to supply at least another 300 years of current demand (International Aluminum Institute 2019, See Relevant Websites section).

However, because of its chemical reactivity it is mostly found in its oxidized form (approx. 250 different minerals exist) and it almost never occurs in purely metallic form.

As a natural mineral alumina, α -Al₂O₃, is rare and it is called corundum. Even rarer is the single-crystal form, sapphire, which is usually slightly colored due to metallic impurities (Ni and Mg give yellow and Ti gives blue) and ruby, which contains a small amount of Cr (≈ 1 wt%).

The most prominent group of aluminum containing minerals is that of the aluminosilicates, and the products of their weathering, the clays. With regards to aluminum production, the aluminum hydroxides represent the most important compounds. Pure anhydrous Al₂O₃ forms two hydrates: Al₂O₃·H₂O (AlO(OH)) and Al₂O₃·3H₂O (Al(OH)₃). Each of these compounds has two

crystalline forms, α and γ and a specific name (diaspore: α - $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$, boehmite: γ - $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$, bayerite: α - $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, and gibbsite or hydrargillite: γ - $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$).

Most alumina grades are originally manufactured from mineral sources. The most significant advancement in terms of raw materials has been the development of chemical routes to fabricate high purity powders with controlled particle sizes.

Small particle size ($\approx 1 \mu\text{m}$ or less) and high purity ($> 99.5\%$) powders are required for the production of high strength and hardness advanced alumina ceramics. For structural applications, especially involving high temperature, and optical and electrical applications, extremely high purity aluminum oxide is needed. In particular, liquid forming agents such as SiO_2 , Na_2O , CaO , etc. should be avoided.

Industrial Processes

The main raw material for alumina is bauxite (named after Les Baux-en-Provence in France), a mixture of the oxide hydrates and clays (aluminosilicates). Impurities are mostly oxides such as SiO_2 and TiO_2 and small amounts (ppm) of the strategic compound Ga_2O_3 and iron oxides which occur as weathering products of low iron and silica bedrock in tropical climatic conditions. The most common mineral constituent of bauxite is gibbsite. Detailed descriptions of bauxite mineralogy are included in a number of text books, e.g., Wells (1984) and summaries can be found in several revisions, e.g., Doremus (1984). Evolution of gibbsite with temperature has been recently studied by neutron thermodiffraction (Rivas Mercury *et al.*, 2006). Deposits of bauxite exist around the world; the largest ones are found in China, Guinea, Australia, Brazil, and Jamaica.

Purification of bauxite to fabricate aluminum and, to a lesser extent, alumina, is done by the Bayer process. Bauxite consumption per ton of alumina has increased in recent years (from around 2.7 tons in 2005) due to declining quality of bauxite resources and now three tons of bauxite are required to produce one ton of alumina and two tons of alumina are required for the production of one ton of primary aluminum metal. However, the energy efficiency of the Bayer process has improved over that period (International Aluminum Institute 2019, See Relevant Websites section).

Fig. 4(a) shows the geographical share of alumina production in 2018 recognized by the International Aluminum Institute; most alumina was produced in China. The major part of alumina is used for the production of aluminum whereas a small part goes to the alumina chemicals industry (Fig. 4(b)). Nevertheless, the alumina chemicals industry has become a global enterprise in

Fig. 4 Alumina production by weight in 2018. Total: 64.336 million tons (a) Geographical share. E + C: Eastern and Central; W: West; rest: non-China (b) Metallurgical (Al production) and chemical (Al_2O_3 production) share. <http://www.world-aluminum.org/statistics/alumina-production/#data>.

which most of the world's major aluminum firms participate. Most applications of alumina chemical products are in the field of ceramics, including refractories, cements and abrasives.

The Bayer process starts by dissolving crushed bauxite in sodium hydroxide under pressure at 300°C to form a supersaturated solution of sodium aluminate at normal conditions of pressure and temperature. The insoluble oxides are then removed and the hydrated aluminum oxide is precipitated as gibbsite by seeding, more frequently, or as metastable bayerite by reduction of pH by carbon dioxide. The precipitated low temperature forms, γ -alumina, are then washed and subsequently dehydrated at 1000–1200°C to fully convert into the stable α -alumina phase. This material is named calcined alumina and typically contains 0.1–0.5 wt% of sodium and calcium oxides. Powders calcined at intermediate temperatures, usually called reactive aluminas, are mixtures of α -Al₂O₃ and transition aluminas. The coarse aggregates made of large alumina single-crystals for the refractory industry (fused alumina) are obtained by fusing and casting reactive alumina powders and crushing the obtained material. Also it can be graded to be used for grinding and abrasives.

The sizes of powders required for the fabrication of high performance ceramics are in the range of microns (μm) while the calcined agglomerates have sizes up to $\approx 100 \mu\text{m}$, even though the sizes of the primary crystals can be smaller than $1 \mu\text{m}$. Therefore, the calcined agglomerates have to be milled down to obtain uniform sized, small particles. A major objective of the calcination step is to obtain soft agglomerates in order to avoid the expensive and polluting process of intensive milling as much as possible. The other main characteristic of the calcined aluminas is the presence of up to 0.5 wt% Na₂O as mentioned above. Low soda calcined aluminas are considered when the Na₂O is lower than 0.05 wt%. Typical specifications of calcined aluminas are given by [Riley \(2009\)](#).

High Purity Alumina Powders

High purity alumina powders with controlled size distributions and reactivity are required for advanced applications. New processes for obtaining high purity powders have been developed since the late 1980s. The most common are based on the decomposition in air of aluminum containing salts such as ammonium aluminum sulfate, (NH₄)₂SO₄·Al₂(SO₄)₃·12H₂O, or aluminum hydroxides. The obtained transition aluminas are then converted into α -alumina by heating at temperatures over 1000°C, which also promotes the growth of the α -alumina particles and the formation of hard agglomerates. Since the early uses of alumina, different ways have been proposed to reduce the temperature of treatment in order to limit the formation of agglomerates. Different additives such as metal oxides ([Messing *et al.*, 1988](#); [Xue and Chen, 1992](#); [Wakao and Hibino, 1962](#)), α -alumina seeds ([Kumagai and Messing, 1985](#); [Messing *et al.*, 1988](#); [Rajendran, 1994](#); [Yoshizawa and Saito, 1996](#); [Yoshizawa *et al.*, 2004](#)), liquid-phase formers ([Shelleman and Messing, 1988](#)), and different organic and non-organic compounds ([Xue and Chen, 1992](#); [Rajendran, 1994](#); [Wu *et al.*, 2002](#)) as well as high energy ball milling ([Tonej *et al.*, 1994](#); [Wang *et al.*, 2005](#)) have proven to be effective to reduce the α -alumina transformation temperature. The hydrolysis of aluminum alkoxide has also been proposed to obtain high purity alumina ([Fujiwara *et al.*, 2007](#)). All these processes are relatively expensive and produce only small quantities of powders that are used only for specific advanced technology applications.

Since the late 1990s, a huge effort has been devoted to fabricate not only high purity but also extremely fine grain aluminas ($\approx 100 \text{ nm}$). In this sense, direct processing of the nanosized and high specific surface transition aluminas to fabricate the bulk material was proposed. [Bowen and Carry \(2002\)](#) published a comprehensive review on colloidal processing of nanoparticles where most issues about the processing of transition aluminas are discussed. Due to the wide potential applications of monohydrates – boehmite (γ -AlOOH), diasporite (α -AlOOH) and pseudoboehmite – as precursors of aluminas for advanced applications such as orthopedic or dental materials, a growing research effort has been focused on their synthesis in recent years, e.g., [Hai *et al.* \(2018\)](#).

Processing of Alumina Materials

One of the consequences of the high melting point of ceramics and, in particular of alumina, is that materials are generally fabricated from powders and not from fused mixtures. Consequently, the general fabrication process includes the processing of the powders to reach a shaped powder form, usually named the green body, and then followed by thermal treatment. The word sintering is used to describe the various phenomena that occur during the thermal treatment ([Leriche *et al.*, 2020](#)).

When the powder compact is heated to a suitable temperature at which the mass transport mechanisms are operative, the porous compact shrinks as a result of the initial misfit of the particles. Apart from shrinkage, grain growth occurs during the process. In some cases, reaction between the constituents occurs which might aid or impede shrinkage. This latter process is fundamental when the sintering aids are needed.

Processing of advanced alumina ceramics has been recently reviewed in a focused encyclopedia chapter ([Baudín, 2014a](#)) and by [Ruy \(2019\)](#). The main issues that determine the properties of alumina materials are summarized in the following sections.

Thermal Stresses

One main issue of single-phase polycrystalline alumina materials are the thermal stresses which originate when cooling from the sintering temperature due to the thermal expansion anisotropy of single-crystal α -Al₂O₃. Different authors have discussed the importance of thermal expansion anisotropy on alumina materials (e.g., [Blendell and Coble, 1982](#)).

The stress level depends on the particular relative orientation of the grain boundaries and they can also arise due to thermal expansion mismatch between the alumina grains and grain boundary impurity phases. Once the stress level reaches the strength of the material, microcracking is favorable if the elastic energy is sufficient to create two new surfaces. Then, for grain sizes above a critical one, microcracking and even complete failure of the component might occur.

In the case of the alumina ceramics with small grain sizes ($< 30 \mu\text{m}$) considered here, the thermal stresses usually remain as residual stresses in the sintered materials and are partially responsible for the dependence of properties such as hardness, fracture toughness and strength on grain size because they add to the externally applied stresses (Mussler *et al.*, 1982; Rice *et al.*, 1981; Bueno and Baudín, 2006a; Bueno *et al.*, 2008; García-Prieto and Baudín, 2010).

The residual stresses created in single-phase polycrystalline aluminum oxide and in composites as a result of its constrained anisotropic thermal contraction can be measured with the technique of piezospectroscopy using the fluorescence from trace Cr^{3+} impurities (Ma and Clarke, 1994; de Portu *et al.*, 2006). Ma and Clarke (1984) claimed that over the range of grain sizes from 2–16 μm the residual stresses exhibit a dependence on grain size consistent with the prediction of the Evans-Clarke model of thermal stress relaxation by grain boundary diffusion when cooling from 1400°C.

Green Processing

Due to the high cost of machining hard materials such as alumina following sintering, near net shape fabrication methods, and green machining are preferable routes.

Green machining after isostatic pressing is used routinely to fabricate insulators. The extreme geometrical requirements for hip and knee implants require intermediate and final machining and final polishing and two or three stage sintering.

The packing structure of the green body determines the development of the microstructure during sintering. In order to obtain high quality materials, the control of the shape forming processes is of prime importance. In order to avoid defects in the green state, dispersion of the powders to bring them into the state that allows the use of the different shaping methods available is needed.

The sintering of submicronic and high purity (99.5%) aluminum oxide powders to near full density (99% of theoretical) was first reported by Cahoon and Cristensen (1956). Nowadays, processing of high performance alumina materials with relative densities close to 100% and controlled grain sizes, using high purity sub-micrometric and nanosized powders (average diameters from $< 50 \text{ nm}$ up to $0.6 \mu\text{m}$) commercially available since the late eighties, is possible. In principle, the fine particle size together with the increased particle curvature would increase the driving force for solid state sintering, reducing the required temperature and, consequently, limiting grain growth. However, fine particles have a larger tendency to agglomerate. Agglomeration hinders locally homogeneous densification as explained first by Lange (1984) and confirmed later for finer raw materials by Xue and Chen (1990). Therefore, the agglomerates in the green body evolve towards differential sintered density areas consisting of large particles or particle assemblies surrounded by low density zones. In order to achieve real benefit from the use of sub-micrometric powders, the relationships between sintering temperature, sintered density, and grain size as a function of spatial homogeneity and grain interfaces have to be known and handled.

A number of different approaches such as dry (preferentially cold isostatic) pressing and various wet shaping methods followed by pressureless sintering have turned out to be applicable not only for obtaining small samples with submicrometer microstructures but also for providing larger sintered corundum components with grain sizes of 0.5–0.6 μm at relative densities $> 99.5\%$ (e.g., Krell *et al.*, 2003).

Tapecasting is used for manufacturing thin-film and thick-film insulator substrates for microchips, thick-film devices, and micro-feedthroughs for bionics.

Ceramic injection molding (CIM) has long been considered the most appropriate green processing method for high-precision alumina components. High technology components that require high-dimensional precision and shape complexity fabricated by CIM include cochlear bionic feedthroughs and slurry pump components.

The main drawback of green processing methods such as tape casting and CIM that require organic binders is the debinding stage that, apart from the time and energy consumption involved, has the risk of causing cracking, especially for bulk pieces fabricated by CIM.

In order to obtain ceramic components with appropriate shapes for specific applications, different additive manufacturing (AM), also known as 3D printing (3DP), techniques are being developed. These techniques are based on the fabrication of the components layer-by-layer, which provides shape flexibility with reduced time and cost, allowing increased customization of products. A recent review on AM techniques for ceramics has been published by Hitesh *et al.* (2019). AM are considered niche technologies, in particular, it has been proposed to fabricate alumina complex shapes to be used as packages for sensors or electronics for room or high temperatures. Examples of the versatility of 3D technologies for shaping alumina components are shown in Fig. 5, in which pure alumina parts fabricated by lithography based ceramic manufacturing (Schwentenwein and Homa, 2014) are shown.

Many applications of materials would benefit from properties similar to those of the single-crystals. When sufficiently large single-crystals or specific shapes are needed, texture-engineered ceramics lead to property values ranging between those of single-crystals and isotropic bulk ceramics. For instance, textured alumina materials might present increased transparency (Pringuet *et al.*, 2016). An updated review of textured ceramics was published by Messing *et al.* (2017).

Sintering

The sintering of dense bodies from relatively pure (>99 wt%) alumina powders has received more attention than that of any other single oxide system. In fact, it was considered as a model system for the analysis of conventional sintering of ceramics including the effect of additives, and of the sintering of ceramics under pressure.

Diffusion of the aluminum and oxygen ions is slow at temperatures below 1000°C. However, both ions diffuse at higher temperatures (>1300°C) allowing the solid state sintering of alumina materials which is the most used process to fabricate alumina parts. In general, it is agreed that diffusion of both aluminum and oxygen occurs by a vacancy mechanism. However, suitable doping is needed for oxygen diffusion. Basic parameters for solid state sintering of alumina were already known in the early 1960s (Coble *et al.*, 1984; Phillips and Shiue, 1984; Coble, 1961, 1962; Shaw and Brook, 1986). Several articles reviewing early knowledge on alumina sintering can be found in Kingery (1984). The contributions to two *International Conferences on Science and Technology of Alumina* are published in two special issues of the Journal of the American Ceramic Society (French and Heuer, 1994; Elsässer *et al.*, 2003), the first of the issues dedicated to R.L. Coble, one of the greatest researchers in alumina who set up the basis for the understanding of sintering mechanisms in alumina materials (Handwerker *et al.*, 1994). The issue from 2003 is especially devoted to the advancements in diffusion and grain growth.

Two main processes occur during solid state sintering: shrinkage (or densification) and coarsening. Surface diffusion, grain boundary diffusion and lattice (or volume) diffusion are the main mechanisms for material transfer. Only the last two lead to shrinkage whereas surface diffusion increases the interparticle contacts and decreases the surface curvature, eliminating smaller grains and reducing the sintering activity. Some additives can decrease the temperature needed for these processes to take place.

Nowadays it is generally agreed that densification in pure and relatively fine (≈ 0.5 – $1\ \mu\text{m}$) alumina powders at moderate to high temperature is controlled by lattice diffusion of the Al^{3+} cations, with an activation energy $Q = 580\ \text{kJ/mol}$ (Rahaman, 2008). However, some work, dealing mainly with fine grained powders, found sintering parameters compatible with grain boundary diffusion (Bernard-Granger *et al.*, 2007). Moreover, sintering of nanoparticles presents specific characteristics due to the extremely high initial specific surface area.

Coarsening in alumina is dominated by surface diffusion with activation energies in the range 230–280 kJ/mol. In fact, in most ceramics grain growth is controlled by drag of the attached porosity, the pores moving by surface diffusion of atoms (Harmer and Brook, 1981).

Kinetic field diagrams can be used to identify mechanisms interacting with shrinkage in order to establish improved temperature cycles for alumina sintering (Raether and Schulze, 2009).

In the conventional sintering process, the green body is subjected to the thermal treatment in absence of other effects. Since the early 1960s, existing technology permits fabrication of dense alumina pieces by pressureless sintering with MgO (Phillips and Shiue, 1984; Coble, 1961, 1962; Shaw and Brook, 1986) or liquid forming additives such as CaSiO_3 or SiO_2 (Phillips and Shiue, 1984).

Pure alumina is susceptible to exaggerated grain growth of a fraction of grains during pressureless sintering. As a consequence, wide distributions of grain sizes and isolated pores trapped within the largest grains are present in the microstructure. The additions of small amounts ($\approx 0.5\ \text{wt}\%$) of MgO allow control of alumina grain growth and MgO-doped alumina can undergo normal grain growth to large sizes ($> 20\ \mu\text{m}$) without pore trapping inside the grains.

CaSiO_3 and SiO_2 doped materials undergo liquid-phase sintering which enhances anisotropic grain growth (Rödel and Glaeser, 1990; Song and Coble, 1990; Gavrillov *et al.*, 2003). Small amounts of titania (TiO_2) can be used as agents for enhancement of alumina sintering and grain growth (Powers and Glaeser, 1997; Chi *et al.*, 2003; Bueno and Baudín, 2006b). Calcium additions above the solubility limit also enhance elongated growth of alumina grains (Sánchez Herencia *et al.*, 2000; Jung and Baik, 2003; Altay and Gülgün, 2003).

Further aid for compact densification during sintering is the use of hydrogen or water rich atmospheres to enhance the diffusion of the gas trapped in the closed pores during the final stages of sintering (Coble, 1962). Fast firing of alumina doped with $\approx 200\ \text{ppm}$ of MgO at 1850°C during 10 min led to a dense and fine grained alumina material (Harmer and Brook, 1981).

A sintering schedule including a high temperature short step followed by a long low temperature step was used to reach relatively high density ($\approx 98.8\%$) keeping the size of the grains under $1\text{ }\mu\text{m}$, about 60% lower than that obtained for conventionally sintered alumina of the same density (Bodisova *et al.*, 2007).

In principle, ceramic nanopowders would permit the use of low sintering temperatures thus keeping small grain sizes in the sintered body (Chaim *et al.*, 2008). The main criterion for achieving high levels of sintering is to start with a high density and homogeneous green body, which is not evident when dealing with nanoparticles due to their high specific surface areas. Specific forming methods for very fine powders have been developed, especially for transition aluminas. Nevertheless, the need to produce real nanostructures for improving the mechanical performance of ceramics is limited to very special conditions, and most technical advances require controlled and dense submicrometer microstructures rather than nanostructures. Furthermore, the use of submicronic powders ($\approx 200\text{ nm}$) and the substitution of dry iso-pressing by a colloidal pressing approach to improve the particle coordination of green bodies can lead to a decrease of the sintering temperature by $200\text{--}250^\circ\text{C}$ (Yu and Lange, 2010; Tallon *et al.*, 2010).

When applying pressure during sintering, shrinkage is accelerated by enhanced pressure generated at the contacts between the grains by the external pressure. However, there is no acceleration of the grain growth because there is no increase of pressure gradient across the grain boundary (Coble and Ellis, 1963). Since the early 1960s, existing technology permits fabrication of fine grained dense pieces by hot-pressing of undoped powders (Phillips and Shiue, 1984; Vasilos and Spriggs, 1963).

Pressure assisted sintering of alumina is usually done uniaxially (usually named hot pressing, HP) by applying directly the pressure to the powder using a graphite die. However, special shapes such as femoral heads cannot be fabricated by uniaxial pressing and isostatically applied pressure is necessary. Originally hot pressing and hot isostatic pressing were only used for high added value components because they were rather expensive techniques limited to small scale production. Since the 1990s, alumina-based cutting tool inserts are routinely fabricated using high temperature pressing at reasonable cost (Bocanegra-Bernal, 2004; Whitney, 1994).

Other techniques of thermal treatment are at the R + D stage and alumina is routinely used as model material. Electric current activated/assisted sintering (ECAS) is a growing class of versatile techniques in which mechanical pressure is combined with electric and thermal fields to enhance interparticle bonding and densification. An updated review on these techniques has been published by Sakka and Grasso (2019). In the case of single-phase ceramics, the specific sintering conditions allow the preservation of initial powder grain size or nanostructure and improvement of the bonding strength. In particular, it has been demonstrated that spark plasma sintering (SPS) or, better named electrical field assisted sintering, is useful for the efficient densification of submicronic alumina ceramics.

Microwave sintering is based on the coupling of the material with the electric field, absorbing the electrical energy in its bulk and transforming it into heat. The coupling behavior depends on the dielectric loss factor of the material which, in the case of pure alumina is very low, thus, it strongly depends on doping elements and impurities. A systematic study on microwave sintering of alumina has been reported by Croquesel *et al.* (2016).

Properties of Alumina Materials

As previously stated, most of the work on the development of alumina materials has been devoted to take advantage of the desired properties of the single-crystals by controlling the microstructure. Porosity and low density grain boundary phases lead to density values of alumina materials lower than those of sapphire.

Nowadays, high purity alumina polycrystalline materials with controlled microstructure – grain sizes and shapes, grain boundaries, porosity – for advanced applications are available.

Elastic and Mechanical Properties

Hardness and creep

As described above, alumina single-crystals are among the hardest oxides. Accordingly, alumina materials present high hardness, which is one of its most important properties for the industry. Typical values for fine grained and dense ($\approx 99\%$ of T.D.) aluminas are around 20 GPa . By comparison, hardness of commercial mullite and tetragonal zirconia (YTZP) materials are $10\text{--}11$ and 12 GPa , respectively. Grain boundary amorphous phases and porosity decrease hardness. Cr_2O_3 doping leads to formation of a solid solution with Al_2O_3 at the grain boundaries which increases the hardness of alumina materials (Bradt, 1967; Ghate *et al.*, 1975).

Hardness measurements are carried out by pushing an indenter into the surface of the materials. Therefore, the distribution of stresses under the indenter is complex and deformation under it is not purely plastic, especially in ceramics with residual stresses such as alumina materials in which cracking might occur. The hardness of alumina materials increases as grain size decreases from $5\text{ }\mu\text{m}$ down to $0.5\text{ }\mu\text{m}$. On the one hand, there is an increasing limitation of microplastic deformation by movement of dislocations and twins (Krell, 1995, 1996). On the other hand, large-grain materials tend to present grain boundary microcracking under localized loads with associated lowering of hardness; a decrease of Vickers hardness from 20 to 17 GPa for an increase of average grain size from ≈ 1 to $\approx 5.5\text{ }\mu\text{m}$ has been reported (Bueno and Baudín, 2006a). In the sub-micrometer range the favorable influence of small grain size decreases because of a growing (and counter-acting) influence of the network of grain boundaries. In fact, nanomaterials exhibit an increasing tendency to microplasticity. Consequently, in order to maintain the desirable high hardness of alumina, grain size should be kept above 100 nm .

Alpert *et al.* (1988) measured hardness as a function of temperature (20–1000°C) for different aluminas, including sapphire and polycrystalline aluminas containing different amounts of second phase. For all materials, they reported a steady decrease in hardness with increasing temperature according to the semi-empirical equation:

$$H = H_0 \cdot (1 - T/T_0) \quad (4)$$

With $H_0 \approx 23$ GPa for sapphire and pure aluminas and $H_0 \approx 16$ –18 GPa for aluminas containing grain boundary amorphous phases. This behavior conformed to a thermally activated slip process, limited by Peierls stresses. At low temperature, the hardness of materials with secondary phases was lower than that of pure alumina, consistent with the softening of the boundary phases. At high temperatures ($\geq 800^\circ\text{C}$) hardness values of all materials were similar, indicating that deformation was controlled predominantly by the Al_2O_3 .

Polycrystalline aluminas experience permanent plastic deformation under load at high temperature (creep). As in the case of other properties, the creep behavior of alumina has been studied more extensively than that of any other crystalline solid, ceramic or metal. Classical studies proposed diffusional creep as the rate-controlling process. A recent review on creep data for over 40 different aluminas (Ruano *et al.*, 2003) concluded that the dominant deformation mechanism in creep of fine-grained alumina is grain boundary sliding (GBS) accommodated by slip. The metallographic evidence for this mechanism is that the initially equiaxed alumina grains remain equiaxed even after extensive deformation, which is incompatible with diffusional creep. The slip accommodation process is related to the sequential steps of dislocation glide and climb. Pure and dense aluminas present high resistance to creep under relatively high stresses (> 20 MPa) up to temperatures over 1200°C .

Elastic properties

Uncracked fine grained alumina materials under load present the typical behavior of brittle materials which is characterized by the absence of significant plastic deformation being linear elastic up to the point of fracture. The relationship between strain and stress is determined by the elastic properties: Youngs modulus, shear modulus and Poissons ratio, from which only two are independent. The elastic properties are determined by porosity and secondary phases. Typical room temperature values of the elastic properties of fine grained and dense alumina materials fabricated by conventional sintering are summarized in Table 3.

Corresponding with the high stiffness of single-crystal $\alpha\text{-Al}_2\text{O}_3$, elastic properties of polycrystalline alumina materials are high compared with other oxides. By comparison, Youngs modulus of ZrO_2 stabilized with 3 mol% of Y_2O_3 (YTZP; Gurauskis *et al.*, 2006) and mullite ($3\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$; Burgos-Montes *et al.*, 2010) are 200–230 GPa.

For uncracked materials, Youngs modulus decreases with density but it is not affected by grain size (Table 3). These observations are common for different alumina materials. Reported Young's modulus values for pure ($> 99\%$), fine grained (2–6 μm) and dense ($\geq 98\%$ of theoretical) alumina ceramics range from 380 to 410 GPa for conventionally sintered materials and up to 400–450 GPa for the optimized hot-pressed and hot-isostatically pressed aluminas. The elastic properties are determined by porosity. As reviewed by Rice (1998) for a number of oxides and, in particular, for alumina, the log-log plot of the relative Youngs modulus, E/E_0 , versus volume fraction porosity, P , up to around 60%, gives a straight line the slope of which, b , depends on pore geometry. The simplest equation that was initially fitted empirically (Spriggs, 1961), is given by:

$$E = E_0 \cdot \exp(-bP) \quad (5)$$

The same kind of relationship is found for the shear modulus. Such relationships are in agreement with the minimum solids area (MSA) models for different pore geometries.

Values of b for E , and the shear modulus, G , reviewed by Rice are shown in Table 4. The value of b is associated with a given fabrication technique because it is determined by the geometry of the pores and the distribution of the continuous phase and porosity.

Youngs modulus of alumina materials decreases slightly with temperature up to temperatures between 900 – 1200°C , depending on the presence and nature of grain boundary phases. Above these temperatures, irreversible plastic deformation starts due to grain boundary sliding which, in most cases, is due to viscous flow of the boundary phase. For the high purity material (data are plotted in Fig. 2), the decrease is slight up to 1200°C , following the classical relationship for common oxides: decrease $\approx 1\%$ every 100°C increase, between room temperature and the softening temperature (Watchman and Lam, 1959; Watchman *et al.*, 2009).

Table 3 Typical room temperature values of elastic properties and strength of fine grained and dense polycrystalline alumina produced by conventional sintering

Reference	Average grain size (SD) μm	Density (SD) % of theoretical	Youngs modulus (SD) GPa	Shear modulus (SD) GPa	Poissons ratio	Strength (SD), 4pb MPa
^a	1 (0.7)	98.8 (0.5)	405 (5)	126 (1)	0.223 (0.004)	480 (32)
^b	3.5 (0.3)	98.1 (0.3)	379 (8)	–	–	456 (29)
	5.5 (0.6)	98.1 (0.5)	375 (6)	–	–	349 (31)

**Fig. 6** Average strength of polycrystalline aluminas of the indicated grain sizes as a function of temperature. (Spriggs *et al.*, 1964).

Fracture

Brittle behavior is characteristic of alumina because the stress level at which fracture starts is determined by the presence of defects which act as stress concentrators leading to catastrophic failure in the material. Thus, the strength of alumina materials is an extremely variable property, which depends on the distribution of defects present at the surface and internally. Descriptions of brittle fracture can be found in different text books (e.g., Jayatilaka, 1979), a review of structural ceramics with specific examples dealing with alumina materials is published in Bueno and Baudin (2007).

Values of strength of polycrystalline aluminas are lower than those of sapphire and are determined by the material defects as well as the surface state and testing conditions. Typical room temperature values of four-point bending strength of fine grained and dense alumina materials fabricated by conventional sintering are summarized in Table 3.

Apart from specific surface or internal flaws introduced in the material during processing (intrinsic flaws) or machining (extrinsic flaws), grain boundaries are weak microstructural features due to lower density of atoms, concentration of impurities and residual stresses that, depending on their sign, might add to the externally applied stress. Therefore, strength of alumina materials decreases as grain size increases. Fig. 6 summarizes the classical work by Spriggs *et al.* (1964) on the variation of strength with grain size for high purity (99.9%) and dense (98% of T.D.) aluminas processed by hot pressing.

Pores are one of the most characteristic intrinsic defects. Strength values of alumina materials, σ_f , follow the same kind of relationship with porosity, P , and strength of the fully dense material, σ_{f0} , as with Youngs modulus (Eq. (5)), as expected from the MSA models:

$$\sigma_f = \sigma_{f0} \cdot \exp(-bP) \quad (6)$$

Values of b for strength of materials processed differently are given in Table 4. Ceramics do not have uniquely defined failure strengths. Instead a range of strength values are found because of the presence of strength-controlling defects of different sizes which follow a probabilistic distribution proposed by Weibull. Such a distribution implies that the measured values are dependent on the effective volume of specimen subjected to stress. Smaller specimens give higher values - this can be visualized by the fact that the presence of larger defects is less probable. Therefore, testing of small specimens such as microcantilever beams gives strength values determined by the intrinsic microstructural parameters. Microcantilever beams of alumina poly-crystals gave strength values about 5 GPa and presented intergranular fracture usually initiated at the grain boundaries (Yahya and Todd, 2012).

When the material was doped with 0.01% C, the fracture mode changed to transgranular and strength values (≈ 8 GPa) were almost double those obtained for pure alumina.

As occurred with the elastic properties, strength values experience also slight decreases with temperature up to a certain point from which a sharp decrease occurs (Fig. 6). When the material contains a significant amount of residual glass, strength determined at relatively low deformation rates might increase near the glass transition temperature (Gitzen, 1970).

A wide range of fracture energy and fracture toughness values of alumina materials are observed depending on the materials and their processing – composition, grain size and porosity – and also testing technique. Since the initial systematic studies done by Claussen *et al.* (1982), the dependence on grain size and test technique in the case of high purity aluminas has been partially attributed to toughening mechanisms. Toughening mechanisms identified in alumina are crack deflection, microcracking, crack bridging and, for extremely large grain sizes, crack branching. Such mechanisms are mainly due to the presence of residual stresses and therefore, highly dependent on grain size. This is revealed by the greater roughness of the fracture surfaces of the larger grain size aluminas. Table 5 summarizes toughness parameters, determined in flexure tests, for dense alumina materials with relatively small grain sizes. For fine grained materials ($d_{50} \approx 2\text{--}8\ \mu\text{m}$) K_{IC} values from 2 to 6 MPa m^{1/2}, K_{I0} values around 2–2.5 MPa m^{1/2} and specific fracture energy values from 10 to 20 J/m² are found. All K_{IC} values are higher than those reported for alumina single-crystals. For similar testing geometries, values determined using semistable and stable fracture tests are lower ($\approx 35\%$) than those

reported for aluminas with similar grain sizes determined from unstable fracture tests because unstable crack extension implies additional energy consumption as compared to the stable one. Also larger notch radius leads to higher K_{IC} . It is well known that double torsion tests always give the highest values as compared to other methods, as observed for alumina.

There are differences between the values of the crack-tip toughness, K_{I0} , reported. For similar testing conditions, this fact can be attributed to differences in fracture mode of aluminas with different microstructures, as total toughness would be the sum of contributions of intergranular grain boundary fracture, cleavage across the easy fracture planes of the single-crystals and the increase in fracture surface due to deflection (Seidel and Rödel, 1997). In fact, reported K_{I0} values determined in air using microcantilever beams notched by focused ion beam (FIB) for individual alumina grain boundaries ($K_{I0} = 0.7 \pm 0.2 \text{ MPa m}^{1/2}$) and grain cleavage ($K_{I0} = 1.5 \pm 0.3 \text{ MPa m}^{1/2}$) are lower than those shown in Table 4 for polycrystalline materials (Norton et al., 2015).

A significant amount of transgranular fracture (20%), independent of the grain size of the material, was reported by Seidel and Rödel (1997) whereas only the largest grains ($> 5 \mu\text{m}$) presented transgranular fracture in the fine-grained alumina tested by Bueno et al. (2008). Additionally, K_{I0} depends on the testing environment because of the possibility of slow crack growth (SCG) in polycrystalline alumina ceramics, which was first reported by Freiman et al. (1973). The basic mechanism for SCG is the stress assisted corrosion by environmental species (especially water) at the crack tip bonds. The group of Chevalier, from INSA (Lyon), has extensively studied the phenomenon of SCG in high purity alumina ceramics used for total hip arthroplasty (Chevalier and Gremillard, 2008; de Aza et al., 2002; Palmero et al., 2014) and found that it is an extremely slow process in air, with crack growth velocities around 10^{-10} m/s for K_I values slightly above K_{I0} ($\approx 2.5 \text{ MPa m}^{1/2}$, Table 5).

As seen in Table 5, values of specific fracture energy for fine grained ($\approx 10 \text{ J/m}^2$) and coarse grained ($\approx 20 \text{ J/m}^2$) materials are both higher than that reported by Wiederhorn et al. (Wiederhorn, 1969; Wiederhorn et al., 1973) for the preferred cleavage plane in alumina single-crystals at room temperature (6 J/m^2). Even in the absence of significant toughening mechanisms, the fracture energies of poly-crystals are higher than those for single-crystals due to the contribution of intergranular fracture, in the same way as crack tip toughness values in poly-crystals are higher than those at the easy cleavage planes.

The similarity between the G_{IC} and 2γ for fine grained alumina (García-Prieto and Baudín, 2010) reveal the absence of significant crack-size dependent toughening phenomena. On the contrary, for the coarse grained alumina, 2γ is much higher ($\approx 55\%$) than G_{IC} revealing toughening processes (Bueno et al., 2008).

The main drawback of the early initial alumina materials was their brittleness and associated lack of strength reliability. The mechanical behavior of alumina materials has constantly improved since the 1960s. The relationship between the fracture strength, σ_f , the critical stress intensity factor in mode I, K_{IC} , and the defect size, a , is given by the fracture criterion:

$$\sigma_f = \frac{K_{IC}}{Y\sqrt{a}} \quad (7)$$

where Y is a geometric constant. Taking into account this relationship, the two possible ways for improving the mechanical behavior are the control (minimization) of defect size and shape distributions and the increase of toughness.

Regarding the control of the distribution of defects, efforts have been directed towards the decrease of the sizes of the microstructural parameters and the homogenization of the microstructure. Actions have included the increase of the purity and the homogenization and decrease of the particle size of the raw materials, the addition of dopants to control grain size as well as the use of advanced sintering techniques. The development of alumina materials for metal machining and seals as well as for biomedical and optical applications has been the driver of such improvements.

The adequate manipulation of the crystalline thermal expansion anisotropy can lead to increased toughness due to crack deflection, crack branching and microcracking during the fracture process acting as toughening mechanisms.

Wear

Wear is the process of removal of surface material through contact with another moving phase or material. It involves a number of different processes: abrasion, sliding, erosion, cutting, and grinding. There is no single property or test that can predict the response to wear of materials under any environment, this response being the result of a combination of material properties and environment. In general, wear resistance requires high hardness, strength and toughness together with chemical inertness in the considered environment. When lubricants or intermittent wear processes are involved, the material should be resistant to thermal shock. In addition, specific microstructural properties are required to minimize the volume loss by wear. High porosity makes a ceramic friable and, thus, low porosity ceramics are required. Intergranular fracture is dominant in the case of anisotropic materials such as alumina and, thus, small grain size is also needed to minimize volume loss. Also, large grains detached from the alumina surface might contribute to third body wear. In the case of sliding wear, the coefficient of friction between the surfaces in contact should be as low as possible.

Wear rates and wear mechanisms are affected, not only by the material characteristics, but also by the severity of the surface contacts. Under sliding wear pure alumina materials experience sharp transitions between initial mild wear and severe wear (Rainforth, 2004). Mild wear is characterized by material removal by plastic grooving and accumulation of subsurface damage. Damage accumulation leads to the increase of internal stresses resulting in grain boundary cracking and grain pull-out, which is known as severe wear. Transition between mild and severe wear occurs after longer times when lower loads and aluminas with smaller grain sizes are involved.

As already described, the crystal structure of alumina is formed by planes of hexagonal close packed oxygen ions that leave octahedrally coordinated sites which are occupied by Al^{3+} ions. As only two thirds of the sites are filled by Al^{3+} , there are available unsaturated oxygen ions in the structure. In wet environments, alumina materials are capable of chemisorption of water molecules, or carboxylic acid molecules through van der Waals bonding. These bonds are stable up to 200°C and create protective layers that reduce the coefficient of friction and, consequently, the sliding wear of alumina materials (Baudín, 2014b; Rainforth, 2004). This represents a significant advantage for alumina bearings or pump components in wet environments.

As observed by Yahya and Todd (2012), the addition of trace amounts of carbon to alumina changes the fracture mode to transgranular and, as a consequence, the resistance to abrasion wear increases by a factor of 2.7 compared with pure alumina of approximately the same grain size.

Thermal Properties

The thermal conductivity of polycrystalline alumina is determined by the high thermal conductivity of sapphire and modified by porosity and impurities. These latter are responsible for the nature and distribution of the second phases and, therefore, for the characteristics of the grain boundaries. The thermal conductivity of alumina is high for an oxide. By comparison, thermal conductivity of dense mullite between room temperature and 400°C is lower than $8 \text{ W}(\text{mK})^{-1}$ while for alumina it ranges from $\approx 30 \text{ W}(\text{mK})^{-1}$ at room temperature to $\approx 15 \text{ W}(\text{mK})^{-1}$ at 400°C (Mezquita *et al.*, 2001). Thermal conductivity decreases as the impurity content increases. Examples of values of room temperature values for commercial aluminas in $\text{W}(\text{mK})^{-1}$ are: 33.0 for extremely pure alumina (min 99.9%) of density 3.92 g/cm^3 , 27.5 for a 98.5% purity alumina of density 3.80 g/cm^3 , and 16.0 for a 85% alumina of density 3.42 g/cm^3 (See Relevant Websites section).

The effect of the anisotropy in thermal expansion of sapphire is not reflected in the thermal expansion of polycrystalline aluminas unless the microstructure is textured. The thermal expansion coefficient is intermediate for an oxide material. By comparison, the average thermal expansion between $25\text{--}800^\circ\text{C}$ for mullite and alumina (Burgos-Montes *et al.*, 2010) are: ≈ 4.1 and $8.4 \times 10^{-6} \text{ K}^{-1}$, respectively, while for magnesia materials it is $\approx 13.5 \times 10^{-6} \text{ K}^{-1}$ (Lee and Rainforth, 1994). The thermal expansion coefficient is mainly determined by the major phase, thus, it is not affected by porosity or the presence of minor secondary phases.

Functional Properties

Electrical

The first commercial uses of alumina ceramics were in electrical applications. Research on electrical properties of alumina was initiated in the 1930s; since then, a wide range of different results have been reported. Updated reviews on electrical properties of alumina can be found in Doremus (2008) and Ruy (2019).

Alumina, as with most ceramics, is an ionic conductor at intermediate temperatures, but shows no ionic conduction at room temperature. Electron conduction occurs in alumina at temperatures over 1200°C .

Alumina materials are well known because of their high electrical resistivity at room temperature which corresponds with the high electrical resistivity of sapphire. It decreases sharply with decreasing grain size, being orders of magnitude lower for polycrystalline alumina than for sapphire (Table 2). Variation of this property with impurities is different depending on their nature.

Even low alumina grades (85% purity) present high direct current resistivity, $\approx 10^{12} \Omega \cdot \text{m}$. Other ceramics with such high resistivity are AlN, BeO, BN, and $\text{BaAl}_2\text{Si}_2\text{O}_8$ (celsian) (Table 2). However, they present drawbacks as compared to alumina: BeO is expensive and toxic, AlN and BN are expensive and, in order to attain high density, have to be hot pressed in controlled atmosphere, and $\text{BaAl}_2\text{Si}_2\text{O}_8$ is a feldspar mineral that is not widely available with controlled properties.

A dopant is a trace impurity added to a crystal lattice to alter its properties. In semiconductor terminology, dopants are known as “acceptors” (electron acceptors) or “donors” (electron donors). When Al, with three valence electrons, is doped with Ti, with four valence electrons, Ti becomes a “donor” dopant and forms a net negative charge in the alumina lattice, “n-type” region, impeding ionic conductivity. Mg, with two valence ions, is an “acceptor” dopant and forms a net positive charge in the alumina lattice, “p-type” region, enhancing ionic conductivity. For instance, doping pure single-crystal alumina with 430 ppm Ti enhanced its resistivity by four orders of magnitude, while doping it with 10 ppm Mg reduced its resistivity by two orders of magnitude (Ruy, 2019). In the same way, Na and the alkali metals reduce resistivity even more strongly than divalent metals such as Mg.

The other electric property of interest of alumina is the high dielectric loss or AC loss tangent, $\tan(\delta)$. This property measures the efficiency of an insulator in high-frequency electromagnetic fields. Low values of this property are necessary in high-frequency applications such as thick-film microelectronics in microwave technology and microwave-transparent windows in microwave generators. Alumina presents very low loss tangent as compared to other electrical ceramics (Table 2). As for optimum electrical resistivity, the alkali content is critical for the loss tangent and, thus, high purity aluminas are needed.

Optical

As a consequence of the properties of $\alpha\text{-Al}_2\text{O}_3$ single-crystals, alumina ceramics might be transparent in different wavelength ranges. Transparent polycrystalline ceramics such as alumina that possess a unique combination of properties – high-temperature dimensional and chemical stability, hardness, strength, and corrosion resistance – are in great demand in high-tech industries,

such as nanophotonics, opto-electronics, (laser technology, radiative heat transfer), aerospace engineering, and safety systems (transparent armor). The main advantages of ceramics over single-crystals are: low production costs, compositional flexibility, possibility of fabricating articles with different shapes (including complex geometries), and large dimensional sizes.

Detailed analysis of the effect of different microstructural and external parameters on the optical behavior of polycrystalline ceramics can be found in the works of [Krell et al. \(2009\)](#) and [Kachaev et al. \(2016\)](#).

Transparent ceramics have a number of different absorbing and scattering centers, such as grain boundaries, impurities, different phases, porosity, oxygen vacancies, and birefringence for noncubic materials such as alumina. Porosity is the most degrading factor for transparency of ceramics. Residual grain boundary phases due to impurities whose refractive index differs from that of the alumina grains reduce the transparency as a result of light scattering. Also, due to the anisotropy of the refractive index of sapphire, the size of the crystals strongly affects the scattering of light. External factors such as the thickness of the component and the quality of the surface treatment also affect transparency. The development of transparent polycrystalline aluminas has required the availability of pure raw materials and the establishment of processing methods to reach high purity and high density fine grain materials. Processing of polycrystalline aluminas for optical applications has been reviewed by [Baudín \(2014a\)](#).

In principle, full density to over 99.9999% of theoretical and grain size refinement below 100 nm will change the dominant light-scattering mechanism in alumina, allowing the material to become transparent. However, to reach such a microstructure would require the use of nanosized powders that tend to agglomerate and experience very large shrinkage during sintering, and even the smallest defect would have to be avoided during the green processing ([Messing and Stevenson, 2008](#)). Optimized green processing methods together with special sintering procedures such as HIP, HP, SPS and high pressure SPS, or combinations of pressureless sintering or vacuum sintering followed by HP or HIP, have allowed the production of materials with submicrometric grain sizes (0.34–0.60 μm) and porosities lower than 0.05% with in-line transmissions in the range 50%–79% depending on processing and surface preparation (e.g., [Krell and Klimke, 2006](#); [Mata-Osoro et al., 2012](#); [Drdlikova et al., 2019](#); [Ratzker et al., 2019](#)). High transmittance is also obtained in alumina with a highly-oriented (104) microstructure processed using an A-plane single-crystal sapphire as template ([Yanga et al., 2019](#)).

Present and Future of Alumina

As has been described throughout, alumina materials with controlled composition and microstructure have unique combinations of properties retained at high temperature – hardness and stiffness, wear resistance, chemical inertness and associated corrosion resistance and sufficient strength; they also present excellent electrical insulating properties and, when fully dense, they can be translucent and even transparent depending on grain size and porosity. The chemical inertness of alumina also allows its use in biological environments, biocompatibility being one of the most valuable properties of alumina.

In addition to such a unique set of properties, alumina raw materials are available at relatively low cost, even the high grade powders with controlled purity and particle characteristics. Moreover, alumina components with wide ranges of shapes and sizes and controlled microstructure can be fabricated by pressureless sintering.

As described in the introduction, widespread commercial applications of alumina commenced from the 1930s. Many of the uses that were incipient at that time are now routine ones and have extended to a wide range of applications. This is the case for wear resistant parts in different industries – mining, textile, food and beverage, papermaking, wood – and of components in corrosive industrial environments – crucibles, tubes, pumps, seals, etc. In particular, alumina and alumina-based tool tips for metal machining are extensively used since the second half of the 20th century. Such applications, that are possible due to the combination high wear and corrosion resistances of alumina and at relatively low cost, were already widespread when [Doremus \(2008\)](#) stated: “These predictions are speculative, but the most promising new applications of alumina will probably be in electronic circuits, optical components and biomaterials”. Nowadays, alumina is a fundamental material for advanced optical, electronic and biological applications in technologies that were emerging at the beginning of the 21st century.

Alumina is the ideal substitute for glass in harsh environments due to its optical properties, together with dimensional stability, chemical inertness and resistance to wear. Optimization of the microstructures - by reducing the grain sizes to the sub-micrometric scale and further density increases – has permitted the evolution from the translucent aluminas used in high pressure sodium vapor lamp tubes to the transparent ones to be used in lasers, health care, armor, high pressure metal halide lamps and electrical devices.

The combination of high electrical resistivity and low dielectric loss with other properties such as dimensional and chemical stability up to 1700°C, high corrosion resistance, sufficient strength and low cost relative to other ceramics with comparable electrical resistivity, makes alumina the most used ceramic as an insulator, as reviewed by [Ruy \(2019\)](#). The first electrical use of alumina was in macro-insulators: spark plug insulators and power transmission systems. Nowadays, alumina is used as a major constituent of insulating substrates in microelectronics because of its dimensional stability and relatively high thermal conductivity together with thermal expansion coefficient similar to Si. Such application started in the 1980s and experienced a dramatic increase together with the rise of the electronics industry. Alumina is also used as an electrical insulating feedthrough seal in advanced electrical devices where dimensional and chemical stability are required. Regarding insulating applications, it is important to highlight that the biological compatibility and inertness of alumina has allowed the development of a whole family of bionic implants – pacemakers, eye, ear implants ... – with alumina feedthroughs. This industry that started in the second half of the 1980s is now a \$25000 million industry in which alumina is the only material for feedthroughs ([Ruy, 2019](#)).

The high wear resistance of alumina and its inertness that makes the alumina wear particles non-toxic are the main drivers for the success of alumina bearings for arthroplasty since the turn of the 21st century, when ceramic arthroplasty was considered only

as a research activity. Currently, the total number of hip bearing components implanted annually in the world is approaching one million, with 55% of them involving alumina (40% alumina-polyethylene and 15% alumina-alumina (Ruy, 2019)).

The requirements and evolution of biomaterials and, in particular, ceramics for arthroplasty have been analyzed in several reviews (Chevalier and Gremillard, 2008; Huet *et al.*, 2011; Hu and Yoon, 2018; Ruy, 2019).

The alumina hip bearings introduced in the 1970s lacked reliability due to unexpected fracture. Processing improvements together with microstructural design has led to alumina materials with high strength and hardness, decreasing dramatically the incidence of fracture. Fig. 7 shows ceramic bearings commercialized by a leading producer of ceramic bearings for arthroplasty, CeramTec, and their microstructures are shown in Fig. 8. Values of the technological properties are summarized in Table 6. For single-phase alumina,

Note: Piconi, C., Porporati, A.A., 2016. Bioinert ceramics: Zirconia and alumina. In: Antoniac, I. (Ed.), Handbook of Bioceramics and Biocomposites. Cham: Springer. doi:10.1007/978-3-319-12460-5_4.

the improvement of the microstructure from the initial materials to that of the third generation ones (Fig. 8(a)) led to higher strength and hardness values and associated dramatic decrease in the failure rate. The high strength of the zirconia toughened alumina (ZTA) material is primarily due to transformation toughening by zirconia particles. Also, ≈ 3 vol% of strontium aluminate platelets (up to 3 μm in length) nucleated in situ provide toughening by crack bridging and crack deflection. Even though this material has slightly lower hardness, the strength increase is sufficient to assure high wear resistance. The failure rate of ZTA hip bearings is extremely low. The extremely good properties of ZTA allow its use in more demanding applications such as knee replacement.

As follows from what has been described and discussed here, there is currently a variety of $\alpha\text{-Al}_2\text{O}_3$ materials used in a wide range of advanced high technology applications. Such materials, that possess unique combinations of properties in the materials world, have been possible by taking advantage of the intrinsic properties of $\alpha\text{-Al}_2\text{O}_3$ single-crystal by manipulating and controlling the final microstructure. Most probably, further research will open up still unimagined possibilities for alumina materials.

Low Thermal Expansion Ceramic and Glass-Ceramic Materials

Pascal Pilate and Florimond Delobel, Belgian Ceramic Research Center, Mons, Belgium

© 2021 Elsevier Inc. All rights reserved.

Introduction

Low thermal expansion ceramic materials are of special interest for applications which require dimensional stability versus temperature and mainly a high resistance to thermal shock and thermal gradients. During a thermal shock, the sudden variation of temperature induces a temperature gradient between the surface and the bulk of the material. The difference in thermal expansion induces a stress which could initiate the fracture of a brittle material. In many applications, materials are submitted to a constant high temperature difference between their two faces, during a long time. The induced stresses may also lead to material degradation.

For example, during fast cooling, the resistance to failure initiation could be related to the first parameter of thermal shock resistance R' (Kingery, 1955):

$$R' = \frac{\sigma_f}{\alpha E}$$

where σ_f is the strength, α is the thermal expansion coefficient and E is the elastic modulus (Young modulus). It is possible to optimize R' by altering the different parameters (increasing σ_f , decreasing α and/or E). However, it is obvious that materials with very low - near zero - thermal expansion exhibit superb resistance to thermal shock and gradients.

There exists a family of oxide ceramic materials which exhibit a low thermal expansion coefficient. Most of them are well known and already used in various applications such as refractory materials (metal working, coke ovens, etc.), automobiles, domestic cookware, etc.

Thermal expansion

The heating of a crystallographic lattice induces an expansion which is due to the increase of the atomic vibration amplitude around their average position. Another rule is that heating leads to more symmetric lattice. For example, in the tetragonal structure, the c/a ratio, where a and c are the length of the lattice parameters, decreases with increasing temperature (Darnell, 1963; Evans *et al.*, 1980; Son *et al.*, 2019).

The thermal expansion coefficient α (TEC) is defined as (Collins and White, 1964):

$$\alpha = \frac{\Delta L}{L_0} \frac{1}{\Delta T}$$

where ΔL is the difference between the length (L) of the material at the temperature T and the initial length (L_0) of the material at the initial temperature (T_0), ΔT is the temperature variation ($T - T_0$). The measurement unit of the TEC is given in K^{-1} . Some examples of TEC of ceramic materials are given in Table 1 and compared with that of a steel material (Carvill, 1993; Routschka and Granitzki, 2000).

The intrinsic value of the thermal expansion coefficient closely depends on the strength of the chemical bonds but also on the crystalline structure. For example, in a cubic lattice, the TEC is the same in the three directions, and the volume coefficient can be approximated by $\alpha_v = 3 \alpha_l$, where α_l is the linear coefficient. Nevertheless, during heating of asymmetric lattices, the atomic vibrations lead to a more symmetric network and the thermal expansion changes with the direction. In some crystals with high anisotropy, this may induce stress and strain, leading to a negative expansion along one axis and a very low or negative average volume expansion.

Moreover, in polycrystalline materials, the macroscopic thermal expansion coefficient value may be linked to the grain size (Kuszyk and Bradt, 1973; Parker and Rice, 1989). In the case of very high crystalline anisotropy expansion, TEC decreases when the grain size increases, as reported in Fig. 1 (Parker and Rice, 1989). This phenomenon is also associated with a hysteresis whose intensity increases when expansion decreases shown in Fig. 2 (Ohya *et al.*, 2017).

The presence of a hysteresis can be explained by material microcracking. After material heating, during cooling, the thermal expansion anisotropy locally induces stresses at the grain boundaries and leads to cracking. This phenomenon only appears when grain size is higher than a size which is called "critical grain size".

Cleveland and Bradt (1978) demonstrated that the critical grain size may be estimated from the equation:

$$(g_s)_{cr} = 14.4 \frac{\gamma_f}{E \Delta \alpha_{max}^2 \Delta T^2}$$

where γ_f is the energy of crack propagation, E is the elastic modulus, $\Delta \alpha_{max}$ is the highest difference of thermal expansion coefficient and ΔT is the temperature difference during the cooling.

Table 1 Average thermal expansion coefficient of some ceramic materials

Material	Linear TEC α (0–1000°C, $K^{-1} \times 10^{-6}$)
Al ₂ O ₃	8.8
MgO	13.5
Mullite (3Al ₂ O ₃ · 2SiO ₂)	5.3
Vitreous silica (SiO ₂)	0.5
Steel (Carvill, 1993)	10.4–12.4

Grain size-microcracking relation for $\text{NaZr}_2(\text{PO}_4)_3$ family ceramics. *Journal of the American Ceramic Society* 76 (2), 487–491. doi:10.1111/j.1151-2916.1993.tb03811.x. Cleveland, J.J., Bradt, R.C., 1978. Grain size/microcracking relations for pseudobrookite oxides. *Journal of the American Ceramic Society* 61 (11–12), 478–481. doi:10.1111/j.1151-2916.1978.tb16121.x. Rice, R.W., Pohanka, R.C., 1979. Grain-size dependence of spontaneous cracking in ceramics. *Journal of the American Ceramic Society* 62 (11–12), 559–563. doi:10.1111/j.1151-2916.1979.tb12730.x.

This equation is generally simplified to give the relation (Yamai and Ota, 1993):

$$(g_s)_{cr} \sim \frac{1}{\Delta\alpha_{\max}^2}$$

The latter has been demonstrated for many materials, as reported in Fig. 3 (Cleveland and Bradt, 1978; Rice and Pohanka, 1979; Yamai and Ota, 1993).

For most materials, it is possible to control the microstructure and to avoid the appearance of microcracking during the fabrication process (firing). However, when the critical grain size is very small, for example in the case of aluminum titanate, it is very difficult, even impossible, to obtain materials without any microcracks.

The microcracks appear in the material during the fabrication process, in particular during cooling after the first heating (sintering). During reheating (first part of Fig. 2) at low temperature, two phenomena contribute to material shrinkage: grain expansion in the cracks and crack healing. Therefore, at the macroscopic level, the thermal expansion is lower than the intrinsic one. It may be very low (after firing at 1400°C), near zero (after firing at 1450°C) or even negative (after firing at 1500°C). At high temperature, microcracks are closed, the slope of the expansion versus temperature curve thus increases and the thermal expansion coefficient is close to the intrinsic one. During cooling, the material shrinks with a high average thermal expansion and the “cooling” curve is “located” below the heating curve (second step of Fig. 2). When the temperature difference is sufficient, microcracking starts and compensates the natural shrinkage. Finally, the two curves join at the initial temperature.

Moreover, microcracking is inevitably associated with a decrease in the mechanical properties such as elastic modulus and strength. Indeed, Cleveland and Bradt (1978) demonstrated that grain-boundary cracking linked to the increase of grain size, results in many properties changes (e.g., decreases) in the material (Fig. 4).

Ceramic Materials

Silica

Silica ceramic materials are mainly manufactured from pure quartzites and quartz (Brunk, 2000, 2001). Silica is used to manufacture “classical” silica bricks which are well known as refractory materials for some special applications. During the fabrication process, the crushed raw materials are pressed and fired at high temperature between 1400 and 1500°C. The β -quartz from the raw materials is transformed to a mixture of α -cristobalite and α -tridymite with some residual quartz. This transformation is associated with volume changes (4%–5%) (Brunk, 2000; Routschka and Granitzki, 2000). Moreover, during cooling and further reheating, the material exhibits very large and sharp volume variations due to polymorphic transformations between high (α) and low crystallographic phases (β). Table 2 presents the mineralogical modifications and associated volume changes of silica as a function

Fig. 4 Variation of (A) elastic modulus and (B) flexural strength with grain size. Reproduced from Cleveland, J.J., Bradt, R.C., 1978. Grain size/microcracking relations for pseudobrookite oxides. *Journal of the American Ceramic Society* 61 (11–12), 478–481. doi:10.1111/j.1151-2916.1978.tb16121.x.

Table 2 Modification and volume changes of SiO_2

Modification changes $\leftrightarrow$ reversible, $\rightarrow$ irreversible	Transformation temperature ($^{\circ}\text{C}$)	Volume change (%)
$\beta \leftrightarrow \alpha$ -quartz	573	0.8–1.3
α -quartz $\rightarrow$ α -cristobalite	1250 ($\approx 1050^a$)	17.4
$\beta \leftrightarrow \alpha$ -cristobalite	≈ 260	2–2.8
α -quartz $\rightarrow$ α -tridymite ^a	≈ 870	14.4
$\gamma \leftrightarrow \beta \leftrightarrow \alpha$ -tridymite ^a	117–163	0.5
α -tridymite $\rightarrow$ α -cristobalite ^a	1470	0
α -cristobalite $\rightarrow$ melt	1713 ± 10	–
α -tridymite $\rightarrow$ melt ^b	1610 ± 10	–
Fused silica $\rightarrow$ α -cristobalite	Above $\approx 1150^a$	≈ 0.9

^aIn presence of impurities.

^bRapid heating.

Note: Brunk, F., 2001. Silica refractories. *InterCeram: International Ceramic Review* 27–30.

of the transformation temperature (Brunk, 2001). Fig. 5 (Brunk, 2000) shows the usual thermal expansion curve of silica bricks resulting from the overlapping and combination of the three single phase curves (Pereira *et al.*, 2014). At low temperature, the material exhibits a very large expansion between room temperature and 600°C . Both during heating and cooling, the materials are very sensitive to thermal shock in this range of temperature. Below 600°C , the installation must be heated and cooled slowly and very carefully. Above 600°C and up to 1400°C , the curve is flat, the thermal expansion is very low and the resistance to thermal shock and gradients is very high. The main verification of this characteristic is the building of coke oven walls which have to

Fig. 5 Thermal dilatation of silica coke oven brick. Reproduced from Brunk, F., 2000. Silica bricks for modern coke oven batteries. *Coke Making International* 12 (2), 37–40.

sustain a high temperature difference between the “firing side” (1400–1450°C) and the “coke side” (1000–1100°C) (Brunk, 2000; Andreev *et al.*, 2017). Silica bricks are also used for glass furnace crowns (Brunk, 2001; Postrach *et al.*, 2009) and also as checker bricks in the top of the blast furnace stoves where sudden temperature differences regularly occur (Schneider *et al.*, 1986; Brunk, 2001; Manivasakan *et al.*, 2010).

Silica melting in electric arc furnaces allows production of “fused” (“amorphous” or “vitreous”) silica. Fused blocks are crushed and the resulting granular material is used to manufacture pressed or slip-cast refractory materials (Routschka and Granitzki, 2000). Materials are either unfired (hydraulically or chemically bonded) or fired at low temperature to avoid or to limit crystallization of cristobalite (Table 2). Fused silica material exhibits a very small, near zero, thermal expansion coefficient: $\alpha \approx 0.6 \times 10^{-6} \text{ K}^{-1}$ (Routschka and Granitzki, 2000). Therefore, fused silica is practically insensitive to thermal shock. However, there are restrictions concerning the temperature in service. From 1150°C, it crystallizes and transforms into cristobalite with polymorphic transformations which inhibit the technical applications of fused silica above this temperature (Table 2). In some cases, hot repair for example, the small expansion (high thermal shock resistance) is only used during installation, bricks transforming in service. Vitreous silica products are used for hot repairs in glass furnaces and coke ovens, where bricks are directly introduced in hot parts without any preheating (Robyn and Deschepper, 1985; Brunk, 2001). Fused silica rollers, are used to transport warm glass panels at the end of the float glass furnace and to convey steel strip inside furnaces at 1100°C. Fused silica is also used for the manufacture of crucibles for silicon melting (Yamahara *et al.*, 2001). Further applications include ladle shrouds and submerged entry nozzles for steel continuous casting. Fused silica materials are also foreseen for a fast “first heating” of coke ovens (Andreev *et al.*, 2017). Due to the low thermal expansion, low thermal conductivity and excellent abrasion resistance of fused silica grains, products of silica could also be used in aerospace applications, for thermal protection systems (Criss, 1991; Mishra *et al.*, 2010). Fused silica castables are used to cast dies for the hot forming of titania and for brazing honeycomb high speed aircraft structures. This material is also used to protect metal structures on launch pads (Criss, 1991). The ceramic tiles of the reusable surface insulation (RSI) of the space shuttle were mainly composed of high purity amorphous silica fibers (Buckley, Strouhal and Gangler, 1981; Korb, 1981; Buckley, 1995; Sziroczak and Smith, 2016).

Cordierite

Cordierite ($2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$), is a ternary compound in the alumina-silica-magnesia system (Keith and Schairer, 1952; Smart and Glasser, 1981). Cordierite materials are generally obtained by solid-state reaction sintering of a mixture of a magnesia precursor (talc, soapstone, magnesium carbonate or chlorite) with alumina and clay (kaolin) powders, at a temperature between 1350°C and 1400°C (Yamuna, 2004). A cordierite chamotte (prefired grains) can be also added to the original composition to limit shrinkage during sintering (Routschka and Granitzki, 2000). The melting temperature of pure cordierite is about 1460°C

Fig. 6 Kaolin-based cordierite catalyst supports included in ceramic honeycomb or monolith type catalyst converter. Reproduced from Heisler, H., 1995. *Advanced Engine Technology*. London: Arnold. Yamuna, A., 2004. Kaolin-based cordierite for pollution control. *Journal of the European Ceramic Society* 24 (1), 65–73. doi:10.1016/S0955-2219(03)00269-3.

(Camerucci *et al.*, 2003). However, due to the proximity of a low melting temperature (1350–1400°C) in the phase diagram, the maximum recommended use temperature is generally lower than 1350°C, depending on the composition and impurities. Cordierite exhibits a low reversible thermal expansion ($\alpha \approx 2.16 \times 10^{-6} \text{ K}^{-1}$) which ensures a very good thermal shock resistance ($\Delta T > 350\text{K}$) (Ikawa *et al.*, 1986; Vepa and Umarji, 1993; Costa Oliveira and Cruz Fernandes, 2002).

Pure cordierite is used in technical ceramic and refractory materials. Its numerous properties (high thermal and chemical stability, good thermal shock resistance and low thermal expansion coefficient) allows alumina to be replaced by cordierite materials for many applications. In the refractory field, this material is often associated with another mineral – generally mullite or in some cases alumina – to improve its refractoriness and mechanical properties (Ibrahim *et al.*, 1995; Chlup *et al.*, 2005; Ariyajinno and Thiansem, 2018). For materials presenting low cordierite content, cordierite can be considered as an additive which allows improvement of the thermal shock resistance.

The main application of cordierite ceramic is as the catalyst support for car exhaust gas purification and as a diesel exhaust gas particle filter. The material consists of a honeycomb structure which is obtained from the extrusion of a plastic mix as shown in Fig. 6 (Heisler, 1995; Yamuna, 2004).

Refractory applications of cordierite materials are kiln furniture, linings for kiln cars, electrical insulators and supports for electrical resistance and heating elements. Cordierite is also used for technical stoneware and porcelain (Chowdhury *et al.*, 2007).

Aluminum Titanate (Tialite)

Tialite or aluminum titanate (Al_2TiO_5) presents the crystalline structure of the pseudobrookite type, with general formula A_2BO_5 , where A is a trivalent cation and B is a tetravalent one. Tialite monocrystal exhibits a high thermal expansion anisotropy, respectively $\alpha_a = 1.18 \times 10^{-6} \text{ K}^{-1}$, $\alpha_b = 1.94 \times 10^{-6} \text{ K}^{-1}$ and $\alpha_c = -0.26 \times 10^{-6} \text{ K}^{-1}$, that leads to an average calculated thermal expansion coefficient of $9.4 \times 10^{-6} \text{ K}^{-1}$ (Zhien *et al.*, 1996). Moreover, due to a very small critical grain size (1–2 μm), all aluminum titanate materials contain microcracks and exhibit a resulting low, near zero or negative thermal expansion (Fig. 1). Also due to microcracking, the expansion curve versus temperature exhibits a hysteresis (Fig. 2), and mechanical properties of this material are low, generally lower than 50 MPa (Wohlfrohm *et al.*, 1992; de Arenas, 2012). Aluminum titanate can be produced by different chemical routes and calcination, but the most conventional method is the solid-state reaction of fine alumina (Al_2O_3) and titanium oxide (TiO_2) powders at a temperature higher than 1300°C (Freudenberg and Mocellin, 1990; Tilloca, 1991; Segadães *et al.*, 1997). Pre-reacted tialite is sintered at a temperature between 1400 and 1500°C. Tialite material can also be obtained by reaction sintering: shaped alumina and titanium oxide powders are heated at a sufficient temperature allowing both reaction and sintering (Buscaglia *et al.*, 1994; de Arenas, 2012). From the chemical point of view, the tialite material is the only stable compound in the Al_2O_3 - TiO_2 system at temperatures higher than 1280°C (Segadães *et al.*, 1998). Practically, it is unstable between 800 and 1280°C (Buscaglia *et al.*, 1994; Segadães *et al.*, 1998). Some additions can improve the stability. For example, the addition of magnesia (MgO) is generally used to promote solid solution with higher chemical stability (Wohlfrohm *et al.*, 1990; Buscaglia *et al.*, 1994). A small quantity (<3%) of silica leads to a small amount of liquid phase during sintering and a slight increase of the mechanical properties which partially compensates the effect of microcracking (Yoleva *et al.*, 2010). The presence of additives in the tialite, as well as their content, also modifies the value of the thermal expansion coefficient (Morishima *et al.*, 1987; Wohlfrohm *et al.*, 1990; Tilloca, 1991; Zhien *et al.*, 1996; Yoleva *et al.*, 2009, 2010; de Arenas, 2012).

Besides a very good thermal shock resistance, tialite exhibits a low wettability with molten metals. A main application is in the non-ferrous metals foundry and especially for aluminum smelting and casting: as crucibles, pouring spouts, riser tubes, ladles, etc. (Takabatake, 1978; Alecu *et al.*, 2002; Ewais *et al.*, 2017). Recently, a group of researchers even demonstrated the possibility to use aluminum titanate in the automotive sector as a filter for light duty diesel applications (Boger *et al.*, 2011).

Low-thermal-expansion polycrystalline zirconyl phosphate ceramic. *Journal of the American Ceramic Society* 68 (5), 273–278. doi:10.1111/j.1151-2916.1985.tb15321.x.

Zirconyl Phosphate and NZP Materials

Zirconyl phosphate

Zirconyl pyrophosphate $(\text{ZrO})_2\text{P}_2\text{O}_7$ exhibits a high thermal expansion anisotropy ($\alpha_a = 3.6 \times 10^{-6} \text{ K}^{-1}$, $\alpha_b = -5 \times 10^{-6} \text{ K}^{-1}$, $\alpha_c = 6.4 \times 10^{-6} \text{ K}^{-1}$) and thus a low average resulting thermal expansion: $1.7 \times 10^{-6} \text{ K}^{-1}$ (Yamai and Oota, 1985; Pilate and Tirlocq, 1994; Pilate *et al.*, 1998). Zirconyl phosphate powder can be obtained from a chemical process followed by a calcination. Final materials are obtained from a classical ceramic process including shaping and sintering at high temperature. Due to its very difficult densification, the sintering of zirconyl phosphate requires a firing temperature near that of decomposition (1600°C). However, the addition of an additive, such as MgO or ZnO, allows this temperature to be reduced to between 1250 and 1300°C by the formation of a liquid phase (Yamai and Oota, 1985; Pilate and Tirlocq, 1994).

Contrary to aluminum titanate, the critical grain size of zirconyl phosphate is relatively high: $G_{cr} \approx 7 \mu\text{m}$ as reported in Figs. 7 and 3 (Yamai and Oota, 1985; Yamai and Ota, 1993). Therefore, it is easy to synthesize a material without any microcracking or with near theoretical thermal expansion as can be seen in Fig. 8 (Yamai and Oota, 1985). Depending on the sintering conditions (additives, temperature and time), Fig. 8 shows it is possible to obtain materials from positive to negative thermal expansion and with or without hysteresis of the thermal expansion curve (Yamai and Oota, 1985).

Zirconyl phosphate is stable up to 1600°C . Dense materials can withstand severe thermal shock with temperature difference higher than 500K . However, heating to a temperature higher than 1200°C leads to an exaggerated grain growth with appearance of defects (microcracking) and a decrease of mechanical properties. This can be hindered by addition of inhibitors such as silica which allows a material to be obtained with higher microstructure stability (Yamai and Oota, 1985; Yamai and Ota, 1987).

Table 3 Thermal expansion and critical grain size of $\text{NaZr}_2(\text{PO}_4)_3$ family of materials

$\text{NaZr}_2(\text{PO}_4)_3$ family	Thermal expansion coefficient ($\text{K}^{-1} \times 10^{-6}$) ^a				
	α_a	α_c	α_{avg} ^b	$\Delta\alpha_{max}$	G_{cr} (μm)
$\text{KZr}_2(\text{PO}_4)_3$	− 4.4	+ 7.6	− 0.4	12.0	5.5
$\text{KTi}_2(\text{PO}_4)_3$	0.0	+ 7.8	+ 2.6	7.8	13
$\text{CaZr}_4(\text{PO}_4)_6$	− 4.8	+ 14.3	+ 1.6	19.1	2.0
$\text{SrZr}_4(\text{PO}_4)_6$	+ 2.6	+ 1.7	+ 2.3	0.9	> 50
$\text{Na}_{0.25}\text{Nb}_{0.75}\text{Zr}_{1.25}(\text{PO}_4)_3$	− 3.4	+ 6.0	− 0.3	9.4	9.0
$\text{NbZr}(\text{PO}_4)_3$	− 3.4	+ 1.2	− 1.9	4.6	21

^aAverage from room temperature to 1200°C.^b α_{avg} was calculated by $\alpha_{avg} = (\alpha_a + \alpha_c)/3$ (Pet'kov and Asabina, 2004).

Ota, T., Jin I., 1989. Yamai Low thermal expansion and low thermal expansion anisotropy ceramic of $\text{Sr}_{0.5}\text{Zr}_{1.5}(\text{PO}_4)_3$ system. Journal of Materials Science 24 (12), 4239–4245. doi:10.1007/BF00544493. Yamai, I., Ota, T., 1992. Thermal expansion of homogeneous and gradient solid solutions in the system $\text{KZr}_2(\text{PO}_4)_3\text{KTi}_2(\text{PO}_4)_3$ Journal of the American Ceramic Society 75 (8), 2276–2282. doi:10.1111/j.1151-2916.1992.tb04495.x.

Due to its high temperature of decomposition (higher than that of cordierite), zirconyl phosphate is a good candidate for applications as a heat-resistant material. It should be noted that its low strength does not allow its use as a structural material (Omori *et al.*, 1992). Zirconyl phosphate materials could be used for applications which require excellent thermal shock resistance and heat resistance (Watanabe and Ohashi, 1989; Limaye, 1996). Moreover, it seems to be attractive for use as mineral ion exchangers for waste treatment (Baetslé and Pelsmaekers, 1961).

NZP materials

NZP products are also materials based on zirconium phosphate. They are based on the main product with chemical formula: NaZr_2PO_4 . The ions Zr^{4+} and P^{5+} can be substituted to obtain products such as: $\text{Na}_{1+x}\text{Zr}(\text{Si}_x\text{P}_{3-x})\text{O}_{12}$, $\text{Na}_{1-x}\text{Nb}_x\text{Zr}_{2-x}(\text{PO}_4)_3$, $\text{Na}_{1+2x}\text{MgZr}_{2-x}(\text{PO}_4)_3$, etc. (Oota and Yamai, 1986; Yamai *et al.*, 1988; Ota *et al.*, 1989; Yamai and Ota, 1992; Pet'kov and Asabina, 2004; Miyazaki *et al.*, 2008).

These materials also exhibit high thermal expansion differences. The expansion difference and the critical grain size depend on the nature and the level of ionic substitutions (Table 3) which leads to crystallographic modifications (Oota and Yamai, 1986; Yamai *et al.*, 1988; Ota *et al.*, 1989; Yamai and Ota, 1992). Table 3 shows that NZP materials exhibit a very large range of thermal expansion anisotropy and critical grain size (Oota and Yamai, 1986; Yamai *et al.*, 1988; Ota *et al.*, 1989; Yamai and Ota, 1992).

Due to their low thermal expansion and high ionic substitutions capacity, NZP materials are especially attractive for many applications such as fast ionic conductors, devices requiring good thermal shock resistance and catalyst supports in automobiles (Agrawal *et al.*, 1991, 1996; Limaye, 1996). These materials are also attractive as host ceramic for nuclear waste immobilization (Scheetz *et al.*, 1994) or as protective coatings for thermal barrier protection (Limaye *et al.*, 1989; Brown *et al.*, 1992; Breval *et al.*, 2000).

Glass-Ceramic Materials

Glass-ceramics are obtained from reheating of special glasses, usually at two different nucleation and growth temperatures, inducing the crystallization of micro-crystals. Resulting materials consist of micro-crystals dispersed in a glassy bonding phase (Stookey, 1960; Donald, 1993; Beall and Pinckney, 2004). They are very interesting materials because they combine both glass properties (optical, zero porosity) and ceramic properties (mechanical, thermal). These properties mainly depend on the crystal nature. The crystallization of low thermal expansion compounds allows materials to be obtained with low average thermal expansion and therefore products exhibit a good thermal shock resistance. Another advantage of a low thermal expansion is the very high dimensional stability with respect to the temperature.

Cordierite

Glass-ceramics are produced whose micro-crystals are cordierite (Rudolph *et al.*, 1991; Chowdhury *et al.*, 2007). For example, Corning® Pyroceram® is a cordierite (see above) type glass-ceramic. It is a strong material, with a high thermal conductivity and a low dielectric constant (Rudolph *et al.*, 1991). Although its thermal expansion coefficient is not very low ($5.7 \times 10^{-6} \text{ K}^{-1}$ in the range 25–300°C), it can withstand high thermal shock. It is also transparent to radar (Orlova *et al.*, 2015). Main uses of cordierite glass-ceramic are as cook ware, tactical missile nosecones, antenna windows, radomes, solid wave guides and hydrospace systems (Beall, 2009; Orlova *et al.*, 2015).

Fig. 9 LAS glass-ceramic cook top panel manufactured by Corning.

LAS Compounds

The $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (LAS) system contains two different stable ternary compounds: β -eucryptite (LAS 1-1-2) and β -spodumene (LAS 1-1-4) (Nordmann and Cheng, 1997; Rebouças *et al.*, 2019). A solid solution exists between β -eucryptite and β -spodumene, and between β -spodumene and silica (up to 1-1-10).

β -eucryptite exhibits a high anisotropy of thermal expansion and a highly negative expansion along the c axis ($\alpha_a = 7.8 \times 10^{-6} \text{ K}^{-1}$, $\alpha_c = -17.5 \times 10^{-6} \text{ K}^{-1}$, from room temperature to 1100°C) (Schulz, 1974). β -spodumene exhibits a low positive expansion along the a axis ($0.9 \times 10^{-6} \text{ K}^{-1}$) which decreases with silica content of the solid solution (up to $0.3 \times 10^{-6} \text{ K}^{-1}$) (Ostertag *et al.*, 1968). The β -eucryptite – β -spodumene solid solution exhibits an average negative thermal expansion (Xia *et al.*, 2012). After crystallization, LAS glass-ceramics contain both spodumene and eucryptite. The control of the crystallization step allows materials to be obtained with thermal expansion coefficients ranging from 0 to $13 \times 10^{-6} \text{ K}^{-1}$. The control of the fabrication process also leads to materials transparent to visible and infrared light. LAS glass-ceramics are used for domestic (cook top panel (Fig. 9), stove windows, cookware) and technical applications (advanced optics for telescope mirror) (Bach, 1995; Pannhorst, 2004; Xiao *et al.*, 2011; Buchner *et al.*, 2013; Kleebusch *et al.*, 2018).

Pollucite

Pollucite, of formula $\text{CsAlSi}_2\text{O}_6$ (Beger and Buerger, 1967), is the most refractory silicate. Its melting point is higher than 1900°C (Bedard *et al.*, 1992; Morena, 1992). At 200°C , this material exhibits an allotropic transformation with a volume discontinuity, but at higher temperature, the thermal expansion is low. The thermal expansion coefficient ranges between 0 and $2 \times 10^{-6} \text{ K}^{-1}$ (Richerson and Hummel, 1972; Kobayashi *et al.*, 1997). The sintering of pollucite could only be performed at temperatures higher than 1700°C (He and Jia, 2013). High densification can be obtained from 1650°C by hot pressing. More recent researches demonstrate the possibility to develop highly dense pollucite at very low-temperature: 1200°C by the use of a geopolymer precursor (He and Jia, 2013) and even temperatures lower than 1000°C by the sintering of the Cs-exchanged form of Na, Ca-LTA type of zeolite (Omerašević *et al.*, 2016). Pollucite is used as a zeolite material, in particular in the field of nuclear applications, thanks to its high capacity to retain a large amount of Cs when it is immersed in a fluid phase (Gatta *et al.*, 2009). It could also be attractive as an additive for the improvement of refractoriness of glass-ceramics for us in high temperature applications. For example, glass-ceramics containing pollucite are used as preform cores in the making of hollow metal castings for aeronautic applications which require the use of very high temperature alloys (super alloys of nickel and cobalt base) (Beall and Rittler, 1973).

Celsian

Celsian (BAS, $\text{BaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) is the only compound of the ternary $\text{BaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (Levin and McMurdie, 1975; Drummond, 1990). This material exhibits a crystallographic change at 1590°C from monoclinic to hexagonal (hexacelsian) crystalline structure. The latter polymorph is then stable from 1590°C to the melting point of Celsian (1760°C) (Lin and Foster, 1968; Hoghooghi *et al.*, 2005). However, hexacelsian could be the first phase which appears during the synthesis and it could remain metastable at room temperature (Schmutzler and Sandhage, 1995; Lee and Aswath, 2000). It exhibits a volume change (3%–4%) at 300°C with a rapid structural change from β -hexacelsian (hexagonal) to α -hexacelsian (orthorhombic) (Schmutzler and Sandhage, 1995). Because it does not present any structural modifications, the most interesting phase is the monoclinic one (Schmutzler and Sandhage, 1995).

This crystalline structure can be promoted by high temperature heating, or use of additives such as SrO which forms SAS ($\text{SrO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$). BAS reacts with SAS to form a solid solution (Bansal, 1998). Partial substitution of BaO by SrO allows the monoclinic phase to stabilize up to above 1600°C (Long-González *et al.*, 2010). Moreover, the addition of mineralizers such as Li_2O , MgO, CaO, NaF and TiO_2 generally enhances the hexacelsian to celsian transformation (Lee and Aswath, 2003). Celsian can be synthesized through a solid-state process and can be densified at temperatures close to 1580°C. Its strength can be up to 100–120 MPa depending on the composition (Bansal, 1998; Sedghi and Dadashian, 2015). Celsian materials are attractive due to their high refractoriness and their low thermal expansion coefficient ($2.29 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$, 20–1000°C) (Hoghooghi *et al.*, 2005). It can also be exploited in glass-ceramic materials, radar nose cones, electrical insulators, porcelain, enamel, high-temperature electromagnetic windows (radomes) and matrix material in ceramic composites for thermostructural applications (Miller, 1976; Lansmann and Jansen, 2001; Hoghooghi *et al.*, 2005; Amritphale *et al.*, 2007; Sedghi and Dadashian, 2015).

Introduction

Silica and alumina are the most used oxides to manufacture ceramic materials, devoted to everyday life or to more technical or functional applications. Within this binary system, mullite occurs as the predominant defined composition, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, exhibiting a congruent melting under atmospheric pressure (Duval *et al.*, 2008; Schneider *et al.*, 2015). The term mullite originates from the Isle of Mull in Scotland (Fig. 1(a)) where the mineral was first discovered by Bowen and Greig (1924). The naturally occurring mullite is found in very few deposits due to the very atypical and harsh conditions (high temperature and low pressure) required for its formation. The main deposits are located in Scotland (Isle of Mull), in Germany (Eifel mountains), etc. In these deposits, mullite resulted from the interactions of superheated magma with alumina-rich sediments, the high temperature metamorphic rocks of the sanidinite facies or the lightning impacts in sandstones leading to aluminosilicate lechatelierite glasses. An illustration of the shape of naturally occurring mullite is provided in Fig. 1(b). Due to the scarcity of mullite deposits, most mullite or mullite-based products are synthesized. The starting materials commonly used to manufacture mullite products are widely abundant on earth, namely: bauxite, kyanite, silica and aluminosilicate materials (kaolin, sillimanite, andalusite, etc).

Mullite has the following general chemical formula $\text{Al}_2^{\text{VI}}(\text{Si}_{2-2x}^{\text{IV}}\text{Al}_{2+2x}^{\text{IV}})\text{O}_{10-x}$ or $\text{Al}_{4+2x}\text{Si}_{2-2x}\text{O}_{10-x}$, where x can vary between 0.2 and 0.9 (corresponding to the range 55–90 mol% or 71–96 wt% of Al_2O_3 respectively) (Fischer *et al.*, 1996). In the first formula, $\text{Al}_2^{\text{VI}}(\text{Si}_{2-2x}^{\text{IV}}\text{Al}_{2+2x}^{\text{IV}})\text{O}_{10-x}$, IV and VI represent the tetrahedral and octahedral locations, respectively, of these cations in the structure of mullites. Accordingly, mullite can be considered as a solid solution within the binary system alumina-silica, whereby the value of x tends to increase with increasing temperature. The most common form of mullite in ceramics is the 3:2 mullite ($x = 0.25$, corresponding to 72 wt% of Al_2O_3). 2:1 mullite can also be obtained in some cases and corresponds to $x = 0.4$ (Aksay *et al.*, 1991; Aryal *et al.*, 2012; Klar *et al.*, 2017). Nevertheless, depending on the starting reagents, the processing route and the sintering temperature, the final mullite phase can be tuned in agreement with the target application. The phases corresponding to $x = 0$ (Al_2SiO_5), namely kyanite, sillimanite and andalusite have not been considered since they tend to form at higher pressure (Belnou, 2002; Duval *et al.*, 2008) (>10 kPa) compared to mullite in the binary system alumina-silica. Nevertheless, these phases are widely abundant and are used as starting materials to produce mullite. Techniques such as sol-gel, hydrolysis, and precipitation, plasma processing and sintering have been used to produce synthetic mullite and mullite-based materials. The great interest of mullite products relies on its good stability (thermal shock, corrosion and chemical resistance) and on the low coefficient of thermal expansion of mullite that promotes its use in high temperature (refractory) and coating (protection against corrosion and oxidation) applications. Almost 5000 papers (including articles and reviews, among which 350 open access papers) have been published in the last century on mullites. Fig. 2 shows the evolution of the number of publications for each year since 1920. Indeed, the top five authors that have been working on mullites are: Schneider H.; Schmücker M.; Moya J-S.; Liu J.; and Pitak N.V. (source = scopus). Indeed from 1920 to 1970, less than 10 papers were published each year and then a significant increase is observed up to 2000 due to the technological advances and industrial development of mullite-based products. In years that are more recent, the research activities on mullites tend to be stable with the number of publications close to 200 each year.

The aim is to present a review on topics related to: (1) the structure and stability of mullite phases; (2) the processing routes to manufacture mullite products; (3) the main properties and applications of mullites.

Crystallography and Stability

Phase Diagram of Mullite

Most ceramics are multicomponent materials and the most stable phase at any temperature will be the one with the lowest free energy, G (Carter and Norton, 2007). Nevertheless, phase diagrams are one of the most important sources of information for the development of ceramic materials. It can be described as a map of the equilibrium phases associated with various combinations of temperature, pressure, and composition. Understanding the phase diagram of a given system is quite useful to understand solidification processes, characterization of compounds, and phases, and for understanding the chemical reactions involving multiple components at different temperatures. Alumina and silica are components of many commercial ceramics and important minerals such as silica, semi-silica, fireclay, low alumina, mullite, high alumina, and corundum; therefore, the phase diagram is one of the most important of all oxide pairs. Shepherd *et al.* (1909) and Bowen and Greig (1924) published the first Al_2O_3 – SiO_2 equilibrium phase diagram. The equilibrium diagram of this system is illustrated in Fig. 3, which shows the composition in weight percent and temperature in degrees Celsius.

Fig. 1 (a) location of Isle of Mull (Scotland) where mullite was discovered and (b) micrograph of naturally occurring mullite from the Eifel mountains (Germany). Reproduced from Schneider, H., Schreuer, J., Hildmann, B., 2008. Structure and properties of mullite-A review. *J. Eur. Ceram. Soc.* 28, 329–344. doi:10.1016/j.jeurceramsoc.2007.03.017.

Fig. 2 Illustration of the growing interest in mullites from the number of published papers over a century (from 1920 to 2020).

According to the result obtained by Bowen and Greig on both natural sillimanite and with a mixture of Al_2O_3 and SiO_2 in the ratio 1:1, when heated to a high temperature and cooled slowly, good corundum crystals were formed. However, in subsequent studies of phase equilibria in the system Al_2O_3 – SiO_2 the 3:2 compound, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, is formed and referred to as mullite. However, as can be seen from the diagram of Fig. 3, there are two eutectics in the system: one between cristobalite and mullite at $\sim 1595^\circ\text{C}$ and the other at $\sim 1840^\circ\text{C}$ between mullite and corundum. As can be seen from the diagram, mullite takes a limited amount of alumina into solid solution. Indeed, within the limited solid solution domain, 3:2 mullite is a phase of alumina and silica with the composition $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ with 72 wt% of alumina, while 2:1 mullite corresponds to the formula $2\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ with 78 wt% of alumina. In specimens prepared with alumina and quartz in the ratio 3:2, homogeneous aggregates of crystals of only one kind (mullite) were obtained at all temperatures up to 1810°C , where melting began. A slight excess of silica caused the formation of some cristobalite below 1545°C and a small amount of glass (from liquid) above 1545°C .

The Al_2O_3 – SiO_2 phase diagram can be used to explain the “classes” of alumina-silica brick in terms of generalized “refractoriness”. These classes are given in Table 1 along with comments on the use of the products (Schacht, 2004).

Fig. 3 Phase diagram for the Al_2O_3 - SiO_2 system. Reproduced from Carter, C.B., Norton, M.G., 2007. Ceramic Materials: Science and Engineering. Springer.

Table 1 Classes of alumina-silica brick explained in terms of the Al_2O_3 - SiO_2 phase equilibrium diagram

Al_2O_3 range in most standards	Common terminology for phases	General performance in the absence of slag corrosion or alkali attack conditions
Less than 50% Al_2O_3	Fireclay (Chamotte) Phases on phase diagram: mullite and glass (can contain "free SiO_2 ")	Usually made from 100% fireclay Highest-quality grades usable to about 1600°C ("super-duty" brick)
50% Al_2O_3 or 60% Al_2O_3	Sillimanite, andalusite, or kyanite Phases on phase diagram: Major phase—mullite and minor phase—glass (can contain "free SiO_2 ")	Cannot be made from 100% clay since clays do not contain sufficient Al_2O_3 . Made from 60% alumina minerals and contain some fireclay. Can be made with bauxite and clay. Can be used in excess of 1700°C
70% Al_2O_3	Mullite Phases on phase diagram: Major phase—mullite. Products made with bauxite contain corundum, mullite and glass	Made either from "bauxitic clay" or calcined bauxite and Clay. Can be used in excess of 1750°C
80% Al_2O_3 and 85% Al_2O_3	Bauxite Phases on phase diagram: The major phase is corundum, with a minor quantity of mullite and glass	Made from calcined bauxite. Usually used in aluminum contact refractories
90% Al_2O_3	Alumina Phases on phase diagram: The major phase is corundum, with a substantial minor quantity of mullite and glass. Bricks for molten iron contact usually contain fused Al_2O_3 for enhanced abrasion resistance	Made from tabular and/or fused synthetic (Bayer process) alumina aggregates. Can be used in excess of 1800°C

Structure and Crystallography of Mullite

The understanding of the structures of mullite is consequently an area of increasing importance and attraction to many researchers in the field of ceramic materials. The mullite crystallization arises between 900 and 1000°C and within this interval of temperature, mullite is found to be weakly crystalline. Some authors point out the formation of a spinel-like transitory phase also, which is associated with the broad X-ray pattern between 20° and 30° in 2θ (for $\text{Cu K}_{\alpha 1}$ radiation). In contrast, in the temperature range 1100 – 1250°C , mullite development occurs predominantly at the cost of disappearance of the broad X-ray pattern due to the spinel phase. The intensity of the mullite XRD peak is therefore increased from 1100°C . At about 1200°C and above, increases in both intensity and crystallinity of mullite are significantly marked. Splitting of the 0.341 and 0.338 nm peak (corresponding to (120) and (210) crystallographic planes respectively) is enhanced, while the other XRD lines become well resolved and similar to the standard pattern of mullite (Chakraborty, 2014). Typical structures of mullite are shown in Fig. 4.

Fig. 4 Different Structural models obtained from the chemical formula $\text{Al}_2(\text{Al}_{2+2x}\text{Si}_{2-2x})\text{O}_{10-x}$, with $x = 0-1$. Reproduced from Aryal, S., Rulis, P., Ching, W., 2012. Mechanical properties and electronic structure of mullite phases using first-principles modeling. *J. Am. Ceram. Soc.* 95, 2075–2088.

The structure of mullite consists of chains of slightly distorted Al-O octahedra which run parallel to the *c*-axis of the orthorhombic unit cell. These chains are linked by discontinuous double chains of Al-O and Si-O tetrahedra with randomly distributed aluminum and silicon atoms (Fig. 5(a) and (b)). The backbone of the mullite structure consists of linear chains of edge-connected AlO_6 octahedra reinforced by TO_4 tetrahedra. Some of the Si ions are replaced by Al according to Eq. (1). The oxygen vacancy causes the neighboring (Al,Si) O_4 tetrahedra chain to contract and to form an Al-O bridge, as indicated by the ions shown in Fig. 5(c).

However, it is generally assumed that in mullite structure there are two types of tetrahedral sites, noted (T) and (T*). The first position (T) is in a regular environment, while the tetrahedron which surrounds the second (T*) is deformed due to the presence of an oxygen atom O^* common to three tetrahedra. The change in stoichiometry 2:1 to 3:2 is achieved by the departure of an oxygen atom in position O (3) which links two tetrahedral units.

The crystal structure of 3:2 mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) is orthorhombic with the space group *Pbam* and unit cell dimensions $a = 7.533 \text{ \AA}$, $b = 7.686 \text{ \AA}$ and $c = 2.8864 \text{ \AA}$ (stoichiometric composition) (Lenz *et al.*, 2019). Table 2 illustrates the summarized structural parameters of different mullite phases compared to phases with $x = 0$ (spinel) and $x = 1$ (sillimanite, andalusite and kyanite) (Burnham, 1963; Angel *et al.*, 1991; Digne *et al.*, 2004; Schneider *et al.*, 2008).

Processing of Mullite

Different types of mullite can be obtained depending on the synthesis procedures. We can consider the three conventional processing routes for mullite, namely: (1) sintering, (2) melting and (3) chemical routes. In addition, plasma processing is used in order to achieve specific additional performance for the final product (oxides or non-oxides) coated with mullite.

Fig. 5 Crystal structure of mullite. (a) View parallel to [001], the shaded area is shown in (b) from a different angle. (b) View parallel to the [110] direction; Red and blue arrows indicate movement of atoms under tensional and compressional stresses, respectively. (c) Polyhedral representations of mullite structure; Si^{4+} is partially replaced by Al^{3+} , requiring the formation of O3 vacancies (large white semitransparent sphere). 1. The sintering route

In this type of processing, solid-state reactions govern the formation of mullite, and tend to lead to the production of 3:2 mullite phase. The sintering route is widely used in the ceramic industry, based on mixtures of bauxite, kaolin and/or kyanite (Carter and Norton, 2007). Such homogeneous mixtures are sintered at temperature up to 1600°C and the final products can obtain between 85 and 90 wt% of 3:2 mullite. Andalusite and sillimanite can also be used instead of kyanite (Birkenstock *et al.*, 2015) in cost-effective methods (using sillimanite beach sand). The use of a small amount of TiO_2 or ZrO_2 can improve the densification and/or final properties of sintered mullite products. The addition of 2–4 wt% of TiO_2 tends to lower the densification temperature of mullite produced by the sintering method, since the maximum bulk density can be reached in the range 1450–1500°C (instead of 1600°C without TiO_2 addition). Such improvement depends on the purity and composition of the starting powders; the more the silica content, the less wt% of added TiO_2 is needed. The densifying interactions in the presence of TiO_2 are:

- An increase of the cation mobility due to the formation of vacancies while substituting Al^{3+} by Ti^{4+} ;
- The occurrence of a liquid phase at the firing temperature, that enhances the diffusion of reactants, particle rearrangement and therefore the removal of porosity from grain boundaries.

The starting particle size distribution, specific surface area and milling time of the batches have a significant influence on the densification temperature and the final properties (such as flexural strength) of sintered mullite products (Birkenstock *et al.*, 2015).

2. The melting route – Fused mullite

Fused mullite is obtained through the crystallization of alumino-silicate melts. In this case, 2:1 mullite is promoted. In the fusing process, it is necessary to mix the correct amount of alumina and kaolin and fuse them in an electric-arc furnace at about 1750°C or higher temperatures. With this process, a product can be obtained with more than 95% of mullite, and the remainder

will be a mixture of alumina and glass (Burnham, 1963). In general, the starting materials for fused-mullite exhibit very low impurity levels. The crystallization of mullite is obtained from the aluminum silicate melts previously cast into ingot molds (cooling of the bath or by Czochralski crystal growth techniques). The cooling rate controls the Al_2O_3 content of the bulk: higher quenching leads to Al_2O_3 -rich mullites.

3. The chemical route

The heat-treatments of organic and/or inorganic precursors are referred to as the chemical route and the obtained mullites are called chemical mullites. These type of mullites are extremely rich in Al_2O_3 and the composition depends mostly on the starting materials. In general, with the sol-gel method, the type of starting precursors can lead to mullites through a single-phase system or by reaction of a diphasic SiO_2 and Al_2O_3 mixture (Lee *et al.*, 2008). Three types of sol-gel precursors have been defined by Schneider *et al.* (1993) regarding the final mullite morphology and stoichiometry. Type I precursors, which are amorphous in the starting preparation, tend to lead to mullite single phase at 980°C . Type II precursors which are based on pseudo-boehmite and non-crystalline silica mixtures lead to the formation of spinel at 400°C and finally to mullite above 1250°C . Type III precursors, which are amorphous in the starting preparation, give rise to a partial conversion into spinel phase near to 980°C and finally to the crystallization of mullite above 1100°C . A combination of sol-gel and solution combustion synthesis (SCS) can also be used to produce mullites or doped mullites. SCS is a chemical route whereby an exothermic redox reaction is performed between an oxidizer (a metal nitrate in general) and an organic fuel reducing agent (urea, glycine, hydrazides, etc.). For the SCS method, the solution is obtained by mixing soluble reagents and an external heat supply is provided in order to promote the ignition of the mixture, leading to the self-sustained reaction. The advantage of combining SCS and a sol-gel method is to ensure a good mixture of the starting materials (allowing also to incorporate a large variety of foreign cations). In addition, the synthesis temperatures of as-prepared mullite powders are reduced (Schneider *et al.*, 1993).

4. Plasma processing and others

Mullite coatings are very interesting for applications as environmental barrier coatings (EBCs) and/or as thermal barrier coatings (TBCs) on metal components. They can be applied on oxide and non-oxide ceramics substrates as well. Mullite barriers act by forming layers of SiO_2 bonds at the interface with the substrates that prevent them from damage due to water or vapor containing atmospheres or corrosive environments at elevated temperatures. These mullite coatings are also known to possess adequate wear or scar resistance properties. Various deposition techniques can be used for processing mullite coatings, namely: chemical vapor deposition (CVD), physical vapor deposition (PVD), flame spraying and air plasma spraying (APS) techniques. The plasma spraying technique appears to be very efficient compared to other methods for producing mullite coatings, regarding the related cost saving and fast coating synthesis (Mekap *et al.*, 2019).

Beside mullite coatings, some studies are focused on the fabrication of highly textured or fiber mullite components. The acicular or needle-like shape can be used to develop ceramic products exhibiting highly anisotropic properties, like mechanical strength, and/or thermal conductivity. Thanks to the needle-like structure of some mullite phases, the preferred orientation along a direction or a plane can be controlled. Topotactic growth of mullite crystals has been reported in literature and offers an interesting route to control the microstructure and final properties of sintered ceramic products (Lecomte and Blanchart, 2006; Deniel *et al.*, 2010; Boussois *et al.*, 2013; Lecomte-Nana *et al.*, 2013). The shape of mullite will have a significant influence on the properties during use. Fig. 6 shows the typical morphology that can be obtained regarding the processing conditions.

Properties and Applications

Properties of Mullite Ceramics

The following sections will emphasize the properties of mullite materials which are relevant for a wide field of its applications. As previously mentioned, interest is still growing for mullite-based materials due to their high-temperature properties such as high thermal stability even in harsh oxidizing environments, low thermal expansion coefficient (CTE) and thermal conductivity that enhances the thermal shock resistance and allows low creep rates (Schneider *et al.*, 2015). Table 3 summarizes some physical properties of mullite compared with those of alumina, sillimanite and kyanite.

Mechanical properties

Depending on the synthesis route, mullite materials also contain a certain amount of residual liquid as glassy phases. Softening temperature and viscosity of these residual amorphous phases dramatically depend on their composition. These characteristics and the distribution of the glassy phase will strongly influence the mechanical properties of mullite products. Typical values of some mechanical properties are provided in Table 3 (Kind *et al.*, 2010; Sarkar, 2016). At room temperature, the higher the alumina content in mullites, the higher are the mechanical resistances. The presence of pores and glassy phases (or other impurities) tend to decrease the mechanical strength of mullite products. In addition, the incorporation of foreign cations in the structure of mullite could significantly improve these mechanical properties. It should be noted that these mechanical properties increase with temperature (Table 4). However it can be noted that high values of fracture toughness and flexural strength are obtained at 1200°C compared to 22°C , which is mainly due to the low porosity of mullite phases (Hammas *et al.*, 2020). Indeed, at 1200°C fracture

toughness and flexural strength are equal to $3.6 \text{ MPa m}^{1/2}$ and 500 MPa, respectively. The latter increase could result from the network of glassy phase and hard inclusions that contribute to arrest and dissipate fracture lines caused by mechanical or thermal stresses (the cracks would require more energy to propagate catastrophically through the ceramic body).

The mechanical properties of mullite ceramics, synthesized under different conditions, were studied by several authors. Liu *et al.* (2020) synthesized mullite ceramics from coal gangue and high alumina refractory solid wastes by using the solid-state

reaction method. This study realized the resource utilization of coal gangue and aluminum wastes, and had certain guiding significance for the resource utilization of other wastes of similar components. The best values of fracture toughness and bending strength of the mullite ceramics prepared in this work were close to $1.82 \text{ MPa m}^{1/2}$ and 71.76 MPa respectively. It was shown that mullite ceramics from the powders exhibited a needle-like interweaving microstructure, after sintering at 1500°C for 3 h and offered good application prospects. Krenzel *et al.* (2019) studied the correlation between different physical properties and thermo-mechanical properties of mullite ceramics. Consequently, they concluded that the elastic properties of the hot isostatically pressed mullite (HIPed) material were very close to the corresponding properties of single crystal mullite, for example, the Young's modulus of single crystal mullite is 221.5 GPa and that of HIPed Al_2O_3 -rich mullite equal to 222.5 GPa .

Over the previous decades, preparation of mullite ceramic foams from fly ash had drawn increasing attention due to environmentally friendly features, which could promote the comprehensive utilization of resources (Chen *et al.*, 2019; Dong *et al.*, 2019; Li *et al.*, 2019; Chen *et al.*, 2020a). Chen *et al.* (2020a,b) improved the mechanical properties of mullite ceramic foams prepared by vacuum infiltration using andalusite, sillimanite and kyanite slurries. Poor mechanical strength (compressive strength equal to 1.5 MPa) and thermal shock resistance (low residual strength) were obtained for such mullite ceramic foams (heated at 1400°C) when kyanite slurries were used as infiltration slurries. However, the mechanical strength and residual strength ratio of the mullite ceramic foams treated with andalusite infiltration slurries reached 2.59 MPa and 49.9% .

Electrical and thermal properties

Besides the excellent mechanical properties at high temperature, mullite ceramics are widely used in electrical insulation and dielectric applications (MacKenzie *et al.*, 2008; Sanad *et al.*, 2014), thanks to their thermal and electrical properties (Table 5) (Harper, 1993; Shackelford, 2016). Recent research investigations indicated that porous mullite ceramics are the most suitable materials for thermal insulation (Gong *et al.*, 2013; Kalemtaş *et al.*, 2018; Zhang *et al.*, 2020).

For example, Zhang *et al.* (2020) prepared nanofibrous porous ceramics by the gel-casting method. The as-obtained mullite material presented low thermal conductivity ($0.0597 \text{ W m}^{-1} \text{ K}^{-1}$) which is recommended for thermal insulation materials. In addition, Kalemtaş *et al.* (2018) prepared layered porous mullite ceramics via the polymeric sponge method: by using a commercial-grade kaolin source as raw material, a three-layer porous specimen was obtained from this study as shown in Fig. 7 with the three colored arrows. This method comprises three steps: (1) the impregnation of a polymeric sponge which exhibits the desired pore size and distribution; (2) the drying of the obtained material; and finally (3) heat treatment is carried out in order to achieve the designed porous ceramic body (the polymeric sponge is burnt out). It was concluded from this work that the obtained ceramic material appeared suitable for applications in the field of heat insulators.

Optical properties

The optical properties of ceramics are naturally affected either directly or indirectly by several factors such as the constituent elements constituting the ceramic, the crystalline symmetry, the microstructure of the ceramic, and changes in the external field. Taking optical transmittance as an example of the optical and physical properties of a transparent ceramic, this depends on the surface roughness due to the degree of polishing of the ceramic surface, and the optical transmittance changes when the scattering of light is different (Sōmiya *et al.*, 2003). Some results obtained from selected studies on optical properties of mullites are presented in Table 6 (Li *et al.*, 2019; Chen *et al.*, 2020a,b). Indeed, Schneider *et al.* (1993) studied the optical transmittance of pressureless-sintered and hot isostatically pressed mullite ceramics in the near infrared (NIR), visible light (VIS), and in the ultraviolet (UV) spectral ranges. They concluded from this work that optically translucent mullite was found suitable for optical windows in the VIS and NIR ranges, particularly at high temperatures. On the other hand, Seong *et al.* (2007) synthesized and examined the optical properties of single-crystalline mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) nanowires using the chloride vapor transport (CVT) process. It was reported that the mullite nanowires could offer good opportunities for highly toughened ceramic, metal, and polymer composites. Islam *et al.* (2017) doped mullite with a very small amount of 0.1 M Er^{3+} in order to study its effects on optical device applications. Consequently, the experimental result revealed that Er^{3+} doped mullite matrix is beneficial for optical applications at room temperature.

Application and use of Mullite Ceramics

Regarding the aforementioned properties of mullites (see Tables 2–4), manufactured mullites products are found in widely distributed low cost applications as well as in technical or particular high added value applications. Accordingly, the literature contains a large number of papers dealing with the fabrication, characterization, and the use of mullite ceramics. This includes

Fig. 7 Macroscopical image of the porous layered specimen fabricated at 1400°C for 5 h. Reproduced from Kalemtaş, A., Özey, N., Aytekin Aydin, M.T., 2018. Processing of layered porous mullite ceramics. J. Aust. Ceram. Soc. 54, 545–555. doi:10.1007/s41779-018-0183-6.

Table 6 Summary of optical transmittances for various mullite products

Type of mullite product	Optical transmittance (%)	Utilization
Pressureless-sintered mullite	20	Optical window material at elevated temperatures
HIPed mullite	VIS (– 40%) and NIR (– 80%).	Optical window material at elevated temperatures
Nanowire mullite	/	highly toughened ceramic, metal, and polymer composites
Er-doped mullite	70	optical applications at room temperature.

traditional technical products such as porcelain, tableware, and refractories, but also advanced materials such as heat exchangers, filters, catalytic converters, substrates, electronic packaging devices, components for optical systems and turbine engines and heat shields (for details, see the following sections).

Traditional mullite ceramics

Pottery and whitewares

Whitewares are traditional ceramic materials which generally make up pottery and porcelain. The raw materials traditionally used in whiteware production mainly are kaolin and/or kaolin clay, quartz, and feldspars. Generally, mullite (3Al₂O₃ · 2SiO₂) is one of the most stable constituents developed in related refractory products and pottery (Mishra and Ningthoujam, 2017). Fig. 8(a) illustrates a mullite pouring cup fabricated by Schaefer Industrial Ceramics, USA. Lee and Iqbal (2001) examined the

Soc.* 21, 2583–2586.

Table 7 Physical properties of mullite-based refractories sintered between 1200 and 1500°C

Refractory	Flexural/Compressive strength (MPa)	Coefficient of thermal expansion ($10^{-6} K^{-1}$)	Thermal conductivity ($W m^{-1} K^{-1}$) at 1200°C
Mullite	30 – 100 (3-points bending)	5.0 – 5.7	≈ 4
Mullite-corundum	60 – 160 (biaxial)		0.3
Mullite-cordierite	180 (compressive)	≈ 4.5	0.06

Note: Kind, M., Martin, H., Stephan, P., *et al.*, 2010. VDI Heat Atlas. Berlin: Springer-Verlag. Sarkar, R., 2016. Refractory Technology: Fundamentals and Applications, first ed. Boca Raton: CRC Press.

microstructural features and the importance of mixing on the nature of the mullite formation and morphologies in porcelain under heat treatments and these are shown in [Fig. 8\(b\)](#) and [\(c\)](#). It was indicated that various forms of mullite occurred in porcelains:

(1) primary (P) mullite (close to 2:1 mullite) which was obtained by decomposition of pure kaolinite under heat treatment at 1000 and 1200°C; (2) secondary (S) mullite (close to 3:2 mullite) which was formed by the reaction of feldspar with clay or clay and quartz (Q); and (3) tertiary mullite which seemed to precipitate from an alumina-rich liquid obtained by dissolution of alumina filler.

[Deutou *et al.* \(2020\)](#) investigated the ability of kyanite particles to control the mullitization process and hinder feldspar vitrification during the sintering of microporous porcelain. Therefore, microporous mullite with multimodal pore size distribution was successfully designed by using kyanite that acted to hinder vitrification at relatively low temperature and improve crystallization between 1200 and 1350°C. Consequently, in this range of temperature, optimum interconnectivity, lower average pore size (1.54 μm), higher specific pore area and elastic modulus (> 20 GPa) were achieved as a result of the control of the mullite grain growth and optimum densification and packing of acicular, fibrous and secondary mullite developed.

[Sanz *et al.* \(2018\)](#) studied the crystalline phases of the mullite content in whiteware, which was obtained by sintering of two different industrial kaolins. The main conclusion of this work was related to the evidence of increasing mullite content in the crystalline fraction of the produced porcelains after faster firing in both blends. The composition of the mullite approaches the stoichiometric composition 3:2, similar to that of mullite in stoneware produced from illite-kaolinite compositions, from thermal transformations of kaolin and from sintered mullite at temperatures of $\sim 1300^\circ C$. In contrast there are no significant changes in the average Al_2O_3 contents (near the stoichiometric composition (3:2)) of the mullites.

In addition, [Sirilar *et al.* \(2019\)](#) examined the different properties of mullite formation and glaze-body fit of sanitary ware bodies, by using pottery stone from Lampang, Thailand as a substitute for kaolin, feldspar, and silica. The results of this study showed that the crystal structure and the improvement of mechanical properties of the body mainly resulted from a higher amount of mullite content. It has been indicated that the sample with 37.7–20.7–41.6 of clay-quartz-feldspar ratio and pottery stone as substitute for 100% silica, sintered at 1200°C exhibited 9.27% total shrinkage, 0.17% water absorption, and 60 MPa flexural strength. In addition, linear thermal expansion and thermal expansion coefficient were lower at 0.34 and $7.07 \times 10^{-6} K^{-1}$, respectively.

Refractories

Refractories (see [Sarkar, 2016](#)) are the products used for any high-temperature processing to insulate the system, to introduce erosion–corrosion–abrasion resistances against the process conditions, and are made mainly from non-metallic minerals. However, diverse requirements may arise from application temperatures, atmospheric conditions that prevail during the processing, mechanical, thermal, chemical, abrading and wear conditions, and so on. Therefore, many of the refractory materials have been developed to meet specific service conditions of particular high temperature processing conditions. To meet this wide variety of application conditions, different classes of refractory materials ([Sarkar, 2016](#)) are required and are being developed as time progresses.

Fig. 9 (a) Mullite bricks and (b) crucible fabricated by Zhengzhou Shennan Refractory China and Kumar Ceramics Private Limited, West Bengal, India, respectively; (c) SEM morphology of mullite brick. Reproduced from Yao, S., Zhou, H., Wu, S., *et al.*, 2020. Microstructure and physical properties of a mullite brick in blast furnace hearth: Influence of temperature. *Ironmaking & Steelmaking: Processes, Products and Applications*, vol. 3. Taylor and Francis pp. 1–7.

In general, the major components of refractories can be represented using the binary Al_2O_3 – SiO_2 phase diagram. However, among of all alumina-silica refractories, mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$), with 71.8 wt% Al_2O_3 , has many advantageous properties, which make it an important material for many industrial fields, its several physical properties indicated in [Table 7](#). In addition, synthetic mullite ($\text{Al}_6\text{Si}_2\text{O}_{13}$) is also used as a raw material for some special alumina refractories, produced by the sintering process or melting. In the process, the initial materials are kaolinitic clay, pyrophyllite ($\text{Si}_4\text{Al}_2\text{O}_{10}(\text{OH})_2$), and muscovite ($\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$), which are enriched in alumina in order to meet the required composition of mullite by the addition of calcined Al_2O_3 ([Sarkar, 2016](#)).

The technology of alumina-silica brick is relatively simplified. However, mullite bricks were primarily used as blast furnace hearth lining materials that feature several advantageous properties ([Fig. 9\(a\)](#)). [Yao *et al.* \(2020\)](#) studied the microstructure and physical properties of a mullite brick under different heat treatments (1150, 1350, and 1500°C for 10 h). From the results of this study, the main composition of mullite brick was reported as mullite and corundum (Al_2O_3) ([Fig. 9\(c\)](#)). The chemical composition of these bricks was reported as mainly constituted by Al_2O_3 (71.46 wt%), SiO_2 (21.76 wt%) with small content of TiO_2 (2.44 wt%). Consequently, there is a minor change in the phase compositions after heat treatments. Although the temperature had no effect on the micro-morphology of the mullite aggregate, it directly affected the microstructure of the mullite matrix. With the increase in temperature, the degree of bonding of fine grains was higher and the bonding phase became smooth in the matrix. In addition, the bonding phase formed between aggregate and matrix was gradually widened and reinforced with the increase in temperature.

Also, crucibles made from mullite refractory have received much attention in recent times ([Fig. 9\(b\)](#)). The mullite-based crucibles are usually synthesized from mixtures of clay minerals and bauxite, aluminum hydroxide or alumina. Kaolinite is the clay mineral most commonly used ([Schneider and Komarneni, 2006](#)). [Martín-Torres *et al.* \(2008\)](#) reported different features of mullite-based crucibles such as processing technology, microstructure and phase analysis. In this work, mullite crystalline phase was synthesized by sintering quartz-tempered kaolinite to temperatures above 1300°C, with primary mullite developing in most of the glass and highly acicular secondary mullite growing in regions fluxed by feldspars. The resulting crucibles indicated superior material properties, including high-temperature strength, creep and thermal shock resistance, and thermal and chemical refractoriness. These trends explained their outstanding success in the international market for applications from at least 1300°C.

Advanced mullite ceramics

Advanced ceramics or engineered ceramics, also previously called industrial ceramics, are various inorganic chemical compounds, not necessarily oxides and silicates, that exhibit improved physical and chemical properties and can be grouped according to their field of application: electrical (e.g., semiconductors, insulators, dielectrics, piezoelectrics and pyroelectrics, and superconductors), optical (e.g., phosphors, lasing crystals, mirrors, and reflectors), magnetics (e.g., permanent magnets), and structural ceramics (Cardarelli, 2018). However, besides the traditional use of mullite as a clay product, for which it is credited with giving superior properties for traditional ceramics, it has become a strong candidate for use as an advanced structural, optical, and functional ceramic in recent decades.

Monolithic mullite ceramics

Monolithic ceramic materials, as typical brittle materials, possess very limited plastic deformation capability (Sōmiya *et al.*, 2003). The characteristics of monolithic mullite ceramics are influenced by the amount, size, and distribution of mullite, and by the occurrence of coexisting phases and porosity (Schneider *et al.*, 2015). Liu *et al.* (2020) investigated the influence of sintering temperature (1200–1500°C) on the microstructural and mechanical properties of monolithic mullite ceramics. In this work, three kinds of mullite powders, including micro-, submicron, and nano-powders, were obtained through physical or chemical methods, and the fabrication of monolithic mullite ceramics with the use of these powders as raw materials were studied. They found that the mullite ceramic produced using submicron-powder became fully dense after being sintered at 1200°C, and exhibited a high flexural strength of 254.7 MPa and fracture toughness of 2.9 MPa m^{1/2}, indicating that low-temperature densification of mullite ceramics could be achieved by enhancing the sintering activity of the mullite powder. Li *et al.* (2016) prepared hierarchical porous mullite monoliths via a sol-gel process accompanied by phase separation. In this process, three different silicon sources are used, hypotoxic tetraethylorthosilicate (TEOS), nontoxic aqueous colloidal silica (Aq), and tetramethoxysilane (TMOS). Consequently, it was found that the relative crystallinity is highest in the TEOS system, and lowest in the aqueous colloidal silica system. In addition, Arzani *et al.* (2018) prepared ceramic monolith microfilters (MF), using kaolinitic clay, for the purification of solid-liquid wastewater. The experimental setup and the membrane module are represented in Fig. 10(a) and (b), respectively. The membrane prepared at a sintering temperature of 1150°C and 5 h dwell time, presented specific properties such as permeation flux of 80.9 kg m⁻² h⁻¹ and NTU rejection of 89.8%, mechanical strength of 5.8 MPa, 49.3% porosity and pore size of 1.2 μm. This material could be used for treating solid-liquid wastewaters.

Mullite fibers

Generally, mullite fibers are widely used in industrial ceramics due to their excellent creep resistance at high temperature, good thermal and chemical stability, low thermal expansion coefficient and good dielectric properties (Schneider and Komarneni, 2006). Zhu *et al.*

Fig. 13 TEM and HRTEM descriptions of the diphasic mullite fibers sintered at (a, b) 1000°C, (c, d) 1200°C and (e, f) 1400°C. Reproduced from Gao, Y., Liu, W., Song, X., *et al.*, 2019. Preparation, characterization and mechanical properties of continuous mullite fibers derived from the diphasic sol-gel route. *J. Sol-Gel Sci. Technol.* 92, 75–83.

(2019) studied different properties of porous and nanofibrous mullite fiber-based ceramics. The specimens shown in Fig. 11 are typical mullite fibrous ceramics processed by infiltration and in situ pyrolysis of organic precursors (dimethyl silicone oil and rubber) followed by sintering at 1500°C for 2 h in air atmosphere. Their diameter and thickness were 33 ± 0.5 mm and 20 ± 0.5 mm, respectively. From this work (Zhu *et al.*, 2019), highly porous mullite fiber-based ceramics with a three-dimensional cross structure were successfully designed and fabricated by a filtration method. Polysiloxane binder was introduced in the bonding system in order to analyze the thermal migration of silica sol and to form more stable nodes in the skeleton. The results showed that all specimens recorded high porosity (74.1%–80.9%), low density (0.554 g/cm^3 to 0.608 g/cm^3) and relatively low thermal conductivity ($<0.14 \text{ W m}^{-1} \text{ K}^{-1}$).

In addition, the fabrication of mullite nanofibrous porous ceramics was investigated using a gel-casting method, in order to further increase the strength of the mullite fibrous ceramics (Zhu *et al.*, 2019); the manufacture flow chart of the mullite nanofibrous porous ceramics is shown in Fig. 12. It has been concluded that mullite nanofibrous porous ceramics exhibit a higher compressive strength (0.837 MPa) compared to that of mullite micron-fibrous porous ceramics (0.515 MPa) with density values of 0.202 and 0.266 g/cm^3 , respectively. From this study, the obtained materials that present the best combination of mechanical and thermal properties can be regarded as potential high-temperature thermal insulators in various thermal protection systems.

Continuous mullite fibers have also attracted considerable attention because of their range of applications such as insulators, filters, catalysts, etc. or as reinforcements for ceramic matrix composites (CMCs). Gao *et al.* (2019) fabricated continuous mullite

Fig. 14 Appearance of sintered mullite ceramic: samples (a)–(d) sintered at 1450°C for 10 min and the precursors calcined at: (a) 800°C, (b) 1000°C, (c) 1100°C, (d) 1400°C. Samples (e) and (f) sintered at 1500°C and at 1550°C, respectively, after precursors calcined at 1000°C. Reproduced from Zhang, G., Wang, Y., Fu, Z., *et al.*, 2009. Transparent mullite ceramic from single-phase gel by spark plasma sintering. *J. Eur. Ceram. Soc.* 29, 2705–2711.

Fig. 15 Schematic illustration of the graphite die used for spark plasma sintering of mullite ceramic powders.

fibers via the diphasic sol-gel route. Aluminum isopropoxide (AIP) and aluminum nitrate (AN) as the alumina sources and colloidal silica as the silica source were the starting materials in this study. According to the TEM and HRTEM results ([Fig. 13](#)), it is noted that the crystal grain sizes increased considerably at higher temperatures. Consequently, at 1000°C ([Fig. 13\(b\)](#)), the formed

γ -Al₂O₃ grains with sizes smaller than 15 nm were delimited by amorphous silica and showed crystallographic orientation in the (200) crystal plane. At 1200°C (Fig. 13(d)) the fibers were composed of mullite grains, γ -Al₂O₃ grains and amorphous SiO₂. Therefore, the mullite grains with sizes ranging from 10 to 50 nm mainly grew in the directions of the (110) and (210) crystal faces and the inlaid tiny γ -Al₂O₃ grains still showed crystallographic orientation in the (200) crystal plane. After sintering at 1400°C, the sizes of mullite grains were larger than 200 nm. Fig. 13(f) indicated that the grains grew in the directions of the (110) and (121) crystal faces. Regarding the results of this study, it was suggested that the as-prepared fibers are ideal candidates as reinforcements for ceramics and have promising application in the field of thermal storage.

Transparent mullite ceramics

Transparent ceramics may represent a topic of interest for many ceramists and also for people outside this community, like laser, lighting, or military optical systems developers (Goldstein *et al.*, 2020). Recently, many ceramics have been reclassified as transparent materials, and the mechanisms that make them transparent have also gradually become clearer (Somiya *et al.*, 2003). Exhibiting optical transparency and other highly desirable properties such as a low thermal expansion coefficient, high strength, and a good thermal shock resistance, mullite can be useful as an ideal optical window material at elevated temperatures (Xiao *et al.*, 2020). Zhang *et al.* (2009) fabricated transparent mullite ceramics via spark plasma sintering (SPS) from monophasic precursors. In this work, the effect of the heat treatments, precursor powders, and sintering parameters on the mullite ceramics were studied. Results showed that the as-sintered samples without any additive, exhibited relative bulk density of above 97.5% and an infrared transmittance of 75%–82% in the wavelength range of 2.5–4.3 μ m. The heat treatments of the precursor powders below 1000°C were unfavorable for the complete elimination of -OH, H₂O, and organic compounds, which had negative effects on the optical properties of the final material. In contrast, the increase of the sintering temperature above 1450°C resulted in the decrease of the transmittance of sintered specimens due to elongated grain growth (Zhang *et al.*, 2009). Fig. 14 shows samples which were sintered at 1450°C for 10 min after calcination at (a) 800, (b) 1000, (c) 1100 and (d) 1400°C. In addition, the samples shown in Fig. 14(e) and (f) were previously calcined at 1000°C then sintered at 1500 and 1550°C, respectively. According to these trends, it was suggested that the best calcination range is 1000°C < T < 1400°C in order to ensure the total removal of organics and avoid the occurrence of low powder surface areas and hard agglomerates (both of which are unfavorable for packing, namely when calcining at 1400°C).

Ren *et al.* (2015) synthesized mullite nano-powders from precursor materials using the sol-gel process and pulsed current heating. In addition, infrared transparent mullite ceramics were obtained by the spark plasma sintering method shown schematically in Fig. 15. From this study, a mullite ceramic was achieved with the following properties: infrared transmittance between 83% and 88% in the wavelength range from 2.5 to 4 μ m, fine grain size of 200 nm, hardness and toughness values equal to 17.82 GPa and 3.6 MPa m^{1/2}, respectively.

Summary

This chapter has reviewed various details regarding mullites, from the crystal structure to synthesis methods and to the final properties and applications. Indeed, these aluminosilicates appear to be very attractive for improving ceramic microstructures and physical/chemical properties for everyday life products as well as for new technology trends and environmental issues. Some clarification on the crystallization relationships with starting phases need to be investigated for the mullite solid solutions. In addition, the implementation of other processing methods including additive manufacturing are open research and development topics for mullite-based materials.

Aluminum Titanate, Structure and Properties

Salvador Bueno, Jaen University, Jaen, Spain

Carmen Baudín, Instituto de Cerámica y Vidrio, CSIC, Madrid, Spain

Introduction

Aluminum titanate (Al_2TiO_5 , hereinafter AT) ceramics are synthetic materials which, owing to the high melting point of AT, low thermal conductivity, low thermal expansion and excellent thermal shock resistance, have a high technological interest. AT ceramics are usually prepared by reactive sintering of alumina (Al_2O_3) and titania (TiO_2) powders, forming a compound of stoichiometric proportions.

AT ceramics are commercially classified as a specialized material commonly used in extreme temperature conditions and found mostly in the non-ferrous molten metal industry, especially in aluminum foundries. They are also used as components of internal combustion engines, exhaust port liners, crucibles for metallurgy and thermal barriers.

The microstructure of AT ceramics, the main feature of which is microcracking along the grain boundaries, strongly determines their main properties. Microcracking occurs during cooling from the sintering temperature, owing to the unusual extreme anisotropy in thermal expansion of the orthorhombic $\beta\text{-Al}_2\text{TiO}_5$ single-crystal. The presence of these microcracks leads to technologically desirable properties such as low thermal expansion and thermal diffusivity of polycrystalline $\beta\text{-Al}_2\text{TiO}_5$ materials. However, many potential applications of these materials are limited due to their moderate to low strength values. Consequently, huge efforts have been, and still are, devoted to the improvement of the mechanical behavior of aluminum titanate materials through composition and microstructural control (solid solutions, grain size and shape control, secondary phases and AT-based monolithic and laminated composites).

In previous reviews (Wohlfromm, 1991; Barrios de Arenas, 2012; Thomas and Stevens, 1989a,b; Kim and Gauckler, 2012) different aspects of AT such as structure, properties, synthesis from reaction sintering of alumina and titania powders and thermal stability have been outlined. The relevance and applications of materials with almost zero thermal expansion due to microcracking and which are, consequently, highly resistant to thermal shock have also been described (Papitha *et al.*, 2014; Mandal *et al.*, 2017; Kim, 2010). Moreover, the extraordinary thermo-mechanical behavior of AT has led to the inclusion of this compound in composite materials with structural applications (Morishima *et al.*, 1986; Padture *et al.*, 1993a; Runyan and Bennison, 1991; Yano *et al.*, 1992). Successful application of aluminum titanate materials is determined by the ability to control the microcracking phenomena, together with the ability to manage the decomposition behavior.

The aim of this chapter is to update the available information, especially with respect to the technological interest of aluminum titanate materials, with an additional focus on improving their mechanical performance through the design of ceramic composites. In this sense, the strategy of developing laminated structures, combining layers of high strength brittle materials such as alumina with layers with a high content of AT, with a significant presence of microcracks, is shown as an effective approach to increase toughness (fracture energy) of these structures (Bueno and Baudín, 2007, 2009).

$\text{Al}_2\text{O}_3 - \text{TiO}_2$ Phase Equilibrium Diagram

The $\text{Al}_2\text{O}_3 - \text{TiO}_2$ phase equilibrium relationships can be described by a simple binary system that has been studied by different authors (Lang *et al.*, 1952; Freudenberg, 1987). The main features of the $\text{Al}_2\text{O}_3 - \text{TiO}_2$ phase equilibrium are summarized in Fig. 1, which displays the stability regions with Al_2TiO_5 as the only intermediate compound, and the existence of two eutectics: between Al_2TiO_5 and Al_2O_3 and between Al_2TiO_5 and TiO_2 . Due to the high AT melting point (in this system no liquid phase appears under 1705°C) the usefulness for the design of refractory materials is evident. In agreement with the equilibrium diagram proposed by Lang *et al.* (1952), Fig. 1 shows that there are two polymorphic forms of aluminum titanate, $\alpha\text{-Al}_2\text{TiO}_5$ (stable between 1860 and 1820°C) and $\beta\text{-Al}_2\text{TiO}_5$ (stable between 1820 and $\approx 1280^\circ\text{C}$).

The transformation from β to $\alpha\text{-Al}_2\text{TiO}_5$ is spontaneous and completely reversible. Below approximately 1280°C , aluminum titanate is unstable and decomposes by eutectoid reaction into $\alpha\text{-Al}_2\text{O}_3$ and rutile- TiO_2 , according to reaction (1) (Buscaglia *et al.*, 1994b):

although there is a kinetic inhibition for such a decomposition which depends on grain size and the incorporation of stabilizing phases (Pohlmann *et al.*, 1975). It is known that some additives (MgO , Fe_2O_3 , SiO_2 , ZrO_2) are able to influence both the thermal stability and the microstructure of aluminum titanate (Kim, 2010; Nagano *et al.*, 1999).

Freudenberg and Mocellin (1987) based on subsequent contributions to the $\text{Al}_2\text{O}_3 - \text{TiO}_2$ diagram, proposed $\beta\text{-Al}_2\text{TiO}_5$ as the only stable compound in the system with a decomposition temperature of $1280 \pm 1^\circ\text{C}$, and described the regions of solid solutions plotted in Fig. 1. The solubility of Al_2O_3 in TiO_2 is about an order of magnitude greater than the solubility of TiO_2 in Al_2O_3 . The solubility of both Al_2O_3 and TiO_2 in Al_2TiO_5 is practically negligible; that is, aluminum titanate can be considered a stoichiometric compound; however, this statement is correct only in an oxidizing atmosphere.

Fig. 1 Phase equilibrium diagram of the $\text{Al}_2\text{O}_3 - \text{TiO}_2$ system Adapted from Freudenberg, B., Mocellin, A., 1987. Aluminum titanate formation by solid-state reaction of fine Al_2O_3 and TiO_2 powders. *Journal of the American Ceramic Society* 70 (1), 33–38. doi:10.1111/j.1151-2916.1987.tb04849.x. The solid solution regions of Al_2O_3 in TiO_2 and negligible solubility of both TiO_2 and Al_2O_3 in AT have also been plotted.

More recently, [Berger and Sayir \(2008\)](#) and [Ilatovskaia et al. \(2017\)](#) discussed a high temperature phase, $\text{Al}_6\text{Ti}_2\text{O}_{13}$, that is not an allotropic form of AT, as described by [Lang et al. \(1952\)](#). This compound would participate as an intermediary phase in the eutectic reaction $\text{L} \rightarrow \text{Al}_6\text{Ti}_2\text{O}_{13} + \text{Al}_2\text{TiO}_5$ instead of $\text{L} \rightarrow \text{Al}_2\text{TiO}_5 + \text{Al}_2\text{O}_3$. In addition, the peritectic reaction $\text{L} + \text{Al}_2\text{O}_3 \rightarrow \text{Al}_2\text{TiO}_5$ at 1850°C is also described ([Ilatovskaia et al., 2017](#)).

The thermal instability of Al_2TiO_5 is one of its disadvantages ([Kim, 2010](#)). Several additives have been employed that demonstrated certain efficiency for stabilizing microstructures ([Wohlfrohm, 1991](#); [Rezaie et al., 2009](#)).

Aluminum Titanate Single-Crystals

Crystalline Structure

Al_2TiO_5 crystallizes in a base-centered orthorhombic structure with the *Cmcm* space group. Although some authors assign a *Bbmm* or *Ccmm* space group, these space groups are identical to *Cmcm* except for an interchange of the *a*, *b* and *c* axes. An elemental cell contains 4 formula units, and this results in a theoretical density of 3.702 g cm^{-3} ([Holcombe and Coffey, 1973](#)). The review by [Thomas and Stevens \(1989a\)](#) highlighted as more significant the cell parameters analyzed by [Austin and Schwartz \(1953\)](#) and [Morosin and Lynch \(1972\)](#).

[Austin and Schwartz \(1953\)](#) showed that aluminum titanate is isomorphic with pseudobrookite, Fe_2TiO_5 (**Fig. 2**). This compound gives the name to a group of complex oxides that can be described by the formula A_2BO_5 (where A is a trivalent ion and B is a tetravalent one), which crystallize with this same structure. In the Al_2TiO_5 structure, each Al^{3+} or Ti^{4+} cation are found in octahedral sites surrounded by oxygen. The double chains of distorted octahedra are parallel to the *c* axis. The degree of distortion increases with the difference between the radii of the cations and, thus, is much greater in Al_2TiO_5 than, for example, in Fe_2TiO_5 or Mg_2TiO_5 , due to the small ionic radius of Al^{3+} ([Wohlfrohm, 1991](#)). As will be discussed later, this degree of distortion of the structure can be related to thermal expansion, enthalpy of formation, and compound stability.

On the other hand, in Al_2TiO_5 there is no preference for the two metallic sites present in the structure (Al^{3+} and Ti^{4+}) that are distributed in the network completely randomly. This behavior contrasts with that of the isomorph Fe_2TiO_5 , in which there is a tendency of Fe^{3+} towards the sites of less distortion. [Ohya et al. \(2017\)](#) point out that this random distribution of cations leads to maximum entropy giving rise to the structure of TA becoming stable at high temperature (above 1280°C) despite the fact that the reaction of AT formation from the mixture of corundum and rutile is endothermic.

Thermal Expansion

Pseudobrookite-type oxides are characterized by a strong anisotropy in thermal expansion, expressed as the difference between the coefficients of expansion of the crystallographic axes with the highest and lowest thermal expansion, $\Delta\alpha = \alpha_{\text{max}} - \alpha_{\text{min}}$. In **Table 1** it is observed that the expansion is very large in the direction of the *c* axis, which corresponds to the direction of double chains of distorted octahedra, moderate in the *b* axis, and negative in the *a* axis. The strong expansion in the *b* and *c* directions has been related to the tendency of oxygen atoms to move towards a position of less distortion with increasing temperature. In addition, the maximum distortion of the octahedra in the pseudobrookite isomorph series (with Al, Ga, and Fe as the trivalent cation) also corresponds to the maximum anisotropy. ([Wohlfrohm, 1991](#); [Bayer, 1971, 1973](#)).

Fig. 2 Crystal structure of Pseudobrookite. Modified from Wikimedia Commons, 2009.

Table 1 Thermal expansion coefficient in aluminum titanate single crystals and polycrystalline materials

Thermal Expansion Coefficient along Crystallographic axes ($\times 10^{-6}\text{K}^{-1}$)	
$\alpha_{a20-520}/\alpha_{a20-1000}$	– 2.9/3.0
$\alpha_{b20-520}/\alpha_{b20-1000}$	10.3/11.8
$\alpha_{c20-520}/\alpha_{c20-1000}$	20.1/21.8
Thermal Expansion Anisotropy ($\times 10^{-6}\text{K}^{-1}$)	
$\Delta\alpha_{20-520}/\Delta\alpha_{20-1000}$	23.0/24.8
Average Crystallographic Thermal Expansion Coefficient ($\times 10^{-6}\text{K}^{-1}$)	
$\bar{\alpha}_{20-520}/\bar{\alpha}_{20-1000}$	9.2/10.2
Macroscopic Thermal Expansion Coefficient ($\times 10^{-6}\text{K}^{-1}$)	
$\alpha_{20-1000}$	1.0/1.5
$\alpha_{20-1000}$	1.5/1.7

As **Table 1** shows, the high crystallographic thermal expansion in the direction of the c axis is not noticeable in the average crystalline coefficient of expansion, $\bar{\alpha}$, which is of the order of magnitude of those of common oxides. There is usually a direct and simple relationship between the macroscopic coefficient of materials, α , and the crystallographic ones. In the case of polycrystalline materials free of texture, that is, with a statistical distribution of crystal orientations, α generally coincides with the average of the coefficients corresponding to the crystallographic axes, $\bar{\alpha}$. However, in **Table 1** it is seen that this is not the case for Al_2TiO_5 . As will be discussed later, the macroscopic coefficient of thermal expansion, α , of AT materials is much lower than $\bar{\alpha}$, and, below 1000°C , it can even be smaller than the average thermal expansion coefficient of silica glass between 20 and 1000°C , $\alpha_{20-1000^\circ\text{C}} = 0.5 \cdot 10^{-6}\text{K}^{-1}$ (Fernández Navarro, 2003).

Fabrication of AT Materials

Aluminum titanate materials can be manufactured from previously synthesized aluminum titanate powder (Padture *et al.*, 1993a; Runyan and Bennison, 1991; Uribe and Baudín, 2003) or from alumina and titania mixtures that produce aluminum titanate by reaction sintering of the mixtures (Bartolomé *et al.*, 1996; Okamura *et al.*, 1989). Fabrication from previously synthesized aluminum titanate powders is significantly more expensive as it implies, not only the previous reaction, but also the grinding and milling of the synthesized powders and their sintering at relatively high temperatures ($> 1300^\circ\text{C}$). On the contrary, the processing of materials in one step, using reaction sintering of alumina and titania, is more interesting in terms of process costs and energy savings. Moreover, the potential contamination of the powders by milling is avoided.

Reaction Sintering of Alumina and Titania Powders

As described above, ($\text{Al}_2\text{O}_3 - \text{TiO}_2$ phase equilibrium diagram) AT is a stoichiometric compound in an oxidizing atmosphere, consisting of one mole of alumina, Al_2O_3 , and one mole of titania, TiO_2 , according to the solid state reaction described by:

This solid-state reaction of titania and alumina is thermodynamically favorable above 1280°C (Freudenberg and Mocellin, 1987, 1988; Kato *et al.*, 1980). This is an endothermic reaction and only the positive contribution of the entropic term due to the random cations distribution makes the existence of AT at high temperature feasible. Thus, as collected and analyzed by Wohlfromm (1991) the molar free energy for the reaction (ΔG°) corresponds to:

$$\Delta G^\circ = \Delta H^\circ - \Delta S^\circ \cdot T = 17000 - 10.95 \cdot T (\text{J} \cdot \text{mol}^{-1}) \quad (3)$$

Where ΔH° and ΔS° are the enthalpy and the standard molar entropy of the reaction and T is the temperature in K. This expression reflects values of free energy of formation considerably lower than those of most ceramic oxides (e.g.: G_T for Al_2O_3 ranges from -1590 to -945 kJ mol for temperatures, $T = 273$ to 2273 K (See Baudin, 2021, this Encyclopedia "Alumina, Structure and Properties").

The solid state formation reaction of Al_2TiO_5 , from the equimolar mixture of alumina and titania powders has been studied by various researchers: (Uribe and Baudín, 2000; Freudenberg and Mocellin, 1987, 1988; Thomas and Stevens, 1989d; Buscaglia *et al.*, 1996b). In general, in all the works it is established that this reaction involves nucleation and growth processes that occur completely in the solid state, with a rapid initial advance of the reaction and a later, slower reaction phase, controlled by the diffusion of a single or various species. However, the identification of nucleation sites for AT has not led to conclusive results.

Nucleation of Al_2TiO_5 not only involves the energy necessary for the creation of a new surface, but also requires additional elastic energy that overcomes the elastic constraint exerted by the unreacted matrix of particles of alumina and titania on the Al_2TiO_5 grains in formation. This is because the formation of AT from Al_2O_3 and TiO_2 produces a volumetric expansion of $\approx 11\%$ (taking into account the theoretical densities from the XRD files of 3.99 g cm^{-3} for $\alpha\text{-Al}_2\text{O}_3$, ASTM: 42-1468, 4.25 for TiO_2 -rutile, ASTM: 21-1276, and 3.70 g cm^{-3} for $\beta\text{-Al}_2\text{TiO}_5$, ASTM: 26-0040).

Most of the works on the reactive sintering of Al_2TiO_5 from the equimolar mixture of TiO_2 and Al_2O_3 powders of different nature (particle size, purity level, ... etc.) describe that the microstructure of the formed Al_2TiO_5 is characterized by a matrix of porous cells of Al_2TiO_5 , separated by cracks, which in many cases contain inclusions of Al_2O_3 and TiO_2 . These investigations cite as basic references the works by Freudenberg and Mocellin (1987, 1988). These authors focus their research on studies on compacts prepared from equimolar mixtures of fine alumina powders ($d_{50} < 0.4 \mu\text{m}$) and fine ($d_{50} < 1.5 \mu\text{m}$) or coarse ($d_{50} < 13 \mu\text{m}$) powders of titania, subjected to treatments of up to 100 h over a wide range of temperatures. Thus, they determined the existence of two types of nucleation and growth as a function of the temperature range. At low temperature ($T < 1327^\circ\text{C}$) they identified two stages of evolution of the reaction: a first nucleation and growth characterized by a limited number of "easy nucleation" sites and the isolated growth of Al_2TiO_5 cells within a porous matrix of non-reacted Al_2O_3 and TiO_2 particles. Formed Al_2TiO_5 cells are equally porous and inside there are inclusions of Al_2O_3 and TiO_2 . The growth of these Al_2TiO_5 cells progresses until the sample volume is completely occupied and, from that moment, the Al_2TiO_5 formation reaction continues in a second stage at much lower speeds, with a significant percentage of the initial unreacted oxides within the Al_2TiO_5 cells remaining in the final compacts. The kinetic data of the first stage are adjusted to an Avrami model that assumes the initial presence of all nuclei and their three-dimensional growth at constant speed (Hulbert, 1967) which would agree that the random nucleation sites of the Al_2TiO_5 cells correspond to impurities. On the other hand, at high temperature ($T > 1427^\circ\text{C}$), almost instantaneous nucleation and growth occurs throughout the compact.

Therefore, Freudenberg and Mocellin (1987, 1988) concluded that nucleation and growth depend on the treatment temperature and attributed it to the elastic energy barrier that exists for the formation of Al_2TiO_5 , due to the increase in volume implied by the formation of this phase. At high temperature, the driving force of chemical origin for the formation of the Al_2TiO_5 is sufficient to overcome this barrier. On the contrary, at low temperature the elastic energy barrier can only be surpassed in the "easy nucleation sites" that constitute the discontinuities of the material. Likewise, they observed that, at low temperature, the limited nucleation allows the existence of metastable diffusion pairs of the type $\text{Al}_2\text{TiO}_5/\text{TiO}_2/\text{Al}_2\text{O}_3$ where TiO_2 exerts a double function as a reagent and fast path for the diffusion of Al in the first stage of the reaction. At high temperature, rapid nucleation leads to $\text{Al}_2\text{O}_3/\text{Al}_2\text{TiO}_5/\text{TiO}_2$. Consequently, due to the slow transport of the initial oxides through the Al_2TiO_5 cells, the growth rate of Al_2TiO_5 by diffusion is apparently slower at high temperatures.

With regard to the densification of these materials, during the first minutes of the heat treatment, when only 1% of the sample is reacted, practically 80%–90% of the final density is reached. In fact, the densification process comes to a halt when $\approx 10\%$ is reacted.

Concerning the control of the microstructure of the materials manufactured by reactive sintering, Buscaglia *et al.* (1994a,b, 1995, 1996a,b,c) conclude that the nature of the alumina powders used in the reaction determines the microstructural evolution of the formed Al_2TiO_5 . On the one hand, by decreasing the diameter of the alumina particles, the size of the Al_2TiO_5 cells increases ($0.8 \mu\text{m Al}_2\text{O}_3$ – $100 \mu\text{m Al}_2\text{TiO}_5$ versus $0.3 \mu\text{m Al}_2\text{O}_3$ – $400 \mu\text{m Al}_2\text{TiO}_5$) and, on the other, the presence of MgO in the initial oxide mixture reduces the size of the Al_2TiO_5 cells ($\approx 200 \mu\text{m}$ without MgO versus $\approx 20 \mu\text{m}$ with MgO). In the case of the observations of Wohlfromm (1991) on compacts prepared from equimolar mixtures of fine powders, the size of the formed Al_2TiO_5 cells is influenced by the heat treatment speed, noting that, although the size of the Al_2TiO_5 cells can be reduced using fast heating rates, this type of treatment is detrimental to the degree of reaction.

In general, aluminum titanate commercial components such as crucibles, tubes, plates, spacers, etc. (Ceramtec®), are fabricated by reaction sintering. As will be discussed below, industrial processes usually lead to incomplete reaction of the powders and commercial materials present a huge variability of microstructures with different amounts of unreacted minor phases. The particular microstructure developed depends on the presence of the stable $\text{Al}_2\text{O}_3/\text{Al}_2\text{TiO}_5/\text{TiO}_2$ structures the formation of which is determined by the characteristics of the starting powders (size, specific surface area and impurities) and the thermal cycle.

AT Powder Synthesis

The potential of aluminum titanate materials as advanced ceramics led to the development of a number of chemical methods involving solution chemistry or vapor phase reactions for the development of high purity powders with controlled size and high specific surface area during the last century. Extensive description of these methods can be found in the work by [Thomas and Stevens \(1989c\)](#).

Most works deal with the fabrication of AT powders by co-precipitation of alkoxide solutions and subsequent thermal treatments. The controlled hydrolysis of the single alkoxides to coat either γ - Al_2O_3 or TiO_2 dispersed particles has also been proposed ([Brugger and Mocellin, 1986](#)) and also that of hydrolysis of titanium isopropoxide in a dispersed alumina sol ([Okamura et al., 1989](#)). Other methods include reaction of aerosols ([Ingebrethsen et al., 1983](#)), the direct evaporation of the solvent ([Hori and Kurita, 1985](#)) from aqueous solutions ([Kato et al., 1978](#)) and reaction of Al_2O_3 and TiO_2 mixtures prepared by chemical vapor deposition (CVD) ([Hori and Kurita, 1985](#)).

Sol-gel processing ([Vioux, 1997](#)) can also lower the temperature for the synthesis of aluminum titanate. Formation of AT at $\sim 600^\circ\text{C}$ can be achieved via non-hydrolytic synthesis ([Andrianainarivelo et al., 1997](#)) and at around 800°C by a synthesis with alkoxides stabilized with acetyl-acetone ([Bonhomme-Courty et al., 1994](#)). Also acid-catalyzed solutions of aluminum and titanium alkoxides have been used to synthesize Al_2TiO_5 films at around 700°C ([Innocenzi et al., 2005](#)). The formation of aluminum titanate at these low temperatures is attributed to a diffusion-limited crystallization process, which takes place in conditions of high homogeneity at the molecular level reached in the material ([Lange et al., 1994](#)).

In general, powders fabricated by all these methods are pure and present good and fast sinterability, as opposition to rather slow conventional reaction sintering from oxides. The main drawback is price and the difficulty for scaling up due to the relatively small batches that can be prepared.

Novel Processing Methods

Different investigations on new synthesis and shaping methods contemplate the study of the behavior of aluminum titanate or of its main precursors (Al_2O_3 and TiO_2) to obtain materials due to their special combination of thermo-mechanical properties. In this sense, additive manufacturing through directed laser deposition (DLD) of alumina-titania mixtures ([Wu et al., 2019](#)) gave rise to ceramic composites in the alumina – aluminum titanate system in variable proportions, observing a crack suppression effect in most of the obtained materials depending on initial titania amount. Crack-free structures with a continuous matrix phase formed of Al_2TiO_5 successfully reached maximum cross-sectional dimension of 30 mm and maximum length of 150 mm ([Niu et al., 2019](#)).

Flash sintering and SPS experiments have also been performed on Al_2O_3 and TiO_2 nanopowder mixtures ([Jha et al., 2016](#); [Yang et al., 2009a](#)) allowing the preparation of bulk ceramic materials with high relative densities in a few minutes. The flash sintering tests also made it possible to identify that the reaction sintering process occurs in two stages, with an initial densification of the starting powders and, then, the AT formation reaction, which takes place at temperatures below the nominal equilibrium phase transformation temperature of 1280°C ([Jha et al., 2016](#); [Borrell et al., 2013](#)).

On the other hand, in the general context of developing environmentally sustainable manufacturing routes, in the case of aluminum titanate materials, the following possibilities have been described: synthesis by reactive sintering from Al-sludge waste and rutile ore as rich sources of alumina and titania instead of pure commercial powders ([Ewais et al., 2017](#)) and the use of a solar furnace to obtain AT granular materials ([Gulamova et al., 2018](#)).

Properties of AT Materials

Table 2 summarizes the main properties of AT compiled from the scientific literature and different industrial suppliers. As already described, the main aspect that determines the special characteristics is the AT crystallographic structure and the strong anisotropy in the coefficient of thermal expansion between its crystallographic directions, which gives rise to the development of high thermal stresses during cooling from the fabrication temperature that are the origins of microcracking. This microstructural characteristic determines all the technological properties of aluminum titanate materials, such as their low thermal conductivity and diffusivity and Young's

Table 2 Main physicochemical and mechanical properties of Al_2TiO_5 materials

Property	Al_2TiO_5
CAS no	12004-39-6
Appearance	Light yellow, gray or white powder
Molecular weight (g mol^{-1})	181.83
Bulk density (g cm^{-3})	3.20 – 3.68
Melting Point ($^\circ\text{C}$)	1860
Young's Modulus, E (GPa)	10 – 20
Vickers Hardness, H_v (GPa)	5
Bending strength, σ (MPa)	4 – 40
Thermal Conductivity, k ($\text{W m}^{-1} \text{K}^{-1}$)	1.5 – 2.5

modulus and, especially, their extremely low thermal expansion coefficient and associated excellent thermal shock resistance. However, the major drawback associated with microcracking is the low strength of AT materials. (Nagano *et al.*, 1999; Ohya *et al.*, 1987).

The main goal in the fabrication of AT components is to achieve a microstructure with a relatively fine microcrack network so as to produce low thermal expansion and sufficient strength.

Microcracking; Critical Grain Size

The microstructural development of aluminum titanate materials is determined by the thermal expansion mismatch between contiguous AT grains of different orientation due to the pronounced crystalline thermal expansion anisotropy. Their fabrication, by reaction sintering of Al_2O_3 and TiO_2 mixtures or solid state sintering of AT powders, requires thermal treatments at temperatures high enough to allow mass transport. Then, any thermal expansion mismatch can be accommodated by mass transport at such temperatures. Contrarily, when the sintered compacts are cooled below the temperatures at which mass transport mechanisms are allowed, the thermal expansion mismatch cannot be accommodated and gives rise to the so-called thermal stresses. Such stresses can initiate microcracking or remain as residual stresses in the cooled materials.

All non-cubic crystalline structures present a certain degree of thermal expansion anisotropy. The formation of microcracks in non-cubic polycrystals due to thermal stresses originated by the thermal expansion mismatch depends on the grain size. According to energy criteria, there is a critical grain size below which the formation of microcracks is inhibited (Kuszyk and Bradt, 1973; Ohya *et al.*, 1987). In general, for pseudobrookites, a critical grain size of around 2–5 μm has been determined (Cleveland and Bradt, 1978) significantly lower than that in $\alpha\text{-Al}_2\text{O}_3$ ($\sim 400 \mu\text{m}$) (Rice and Pohanka, 1979).

For the critical grain size of aluminum titanate, there are values in the literature in the range 1–4 μm . The dispersion of these values is probably due to the different criteria used to determine the critical size. For example, Ohya *et al.* (1987) determined a critical size by the abrupt change in mechanical resistance as a function of grain size, while Parker and Rice (1989) made use of the increase in the coefficient of thermal expansion. In summary, it is an effective critical grain size, that is, the minimum grain size necessary for a sufficient amount of microcracks to occur to produce a significant effect on the properties of the material.

During processing AT ceramics, the starting composition and characteristics of the powder raw materials and the temperature and duration of the sintering thermal treatment are key factors that lead to different microcracked microstructures. As an example, Fig. 3 shows two characteristic microstructures of commercial AT materials. Both materials have aluminum titanate as the major phase and rutile as a minor phase (white in the SEM micrographs), while in material (b) alumina traces were also detected. Material (a) consists of relatively small AT regions and a high density of small cracks as compared to material (b), with a lower density of larger cracks and larger AT regions.

The main way to control these cracks and defects is by introducing additives to AT. Different authors point that the addition of dopants such as MgO , or Fe_2O_3 , which are isomorphous with the mineral pseudobrookite, limits microcracking in AT materials (Maki and Suzuki, 2013; Kornaus *et al.*, 2019). Another possibility for controlling the microcracking phenomenon is to add suitable second-phase particles like Al_2O_3 , ZrO_2 or mullite (Sarkar *et al.*, 2015, 2016). Sintering temperature also has an inversely proportional relationship with the mechanical properties and thermal expansion coefficient, in which an increase in the former causes a reduction in the latter properties (Li *et al.*, 1995).

Thermal Expansion and Thermal Diffusivity

As stated previously, the macroscopic coefficient of thermal expansion, α , of AT materials is much lower than the average crystallographic CTE, $\bar{\alpha}$, and it is highly dependent on composition, grain size, thermal history, etc. Buessem and Lange

Fig. 3 Characteristic microstructures of commercial aluminum titanate materials. Extensive microcracking is observed. Both materials have aluminum titanate as major phase (gray) and rutile as minor phase (white). In material (b) alumina traces were also detected by XRD.

Fig. 4 Characteristic curves of thermal expansion of two AT materials whose microstructures are shown in Fig. 3. The hysteresis between the heating and cooling treatments is observed.

(1966) were the first researchers that performed a careful analysis on the effect of microcracks due to the thermal expansion anisotropy on the properties of AT, in particular, in the thermal expansion coefficient. Lately, this subject has been investigated by a number of researchers (Bruno *et al.*, 2010; Kim and Cao, 2002; Giordano *et al.*, 2002; Kim and Kim, 2004; Ohya *et al.*, 2017).

As shown in Table 1, AT materials have much lower coefficients of thermal expansion than the crystallographic average. Moreover, the expansion behavior presents strong hysteresis between heating and cooling, as shown in the characteristic thermal expansion curves Fig. 4 of the commercial materials whose microstructures are shown in Fig. 3. Material (a), with a high amount of smaller microcracks presents lower overall thermal expansion and higher thermal expansion hysteresis than material (b), with lower density of larger microcracks. The observed hysteresis is appreciable even in thermal cycles between room temperature and 400°C, and the hysteresis area increases progressively with the maximum temperature of the treatment.

The microstructural origin of the thermal expansion behavior of AT polycrystals can be described as follows. At room temperature, sintered Al_2TiO_5 bodies contain remarkable amounts of microcracks at the grain contacts. Most of them are perpendicular to the crystallographic axes with the highest coefficients of expansion, *b* and *c*, while the grain-grain contacts perpendicular to the axis, *a*, remain intact. Such microstructural features explain the thermal expansion curves of AT materials, according to the scheme of Fig. 5, by reversible micro-processes of recombination of microcracks (crack healing during heating) and formation of microcracks (microcracking during cooling).

When heating Al_2TiO_5 ceramics that already contain a certain amount of microcracks, the crystallites expand on a microscopic scale in directions *b* and *c*, filling the volume of microcracks, and contract in direction *a*; As a consequence, the piece does not initially experience any dimensional change or may even undergo a slight contraction (first section during heating in Fig. 4). From about 300–400°C the body begins to expand and the coefficient of expansion increases gradually. This section of the expansion curve becomes controlled by the expansion of the recombined material according to the crystallographic expansion coefficients. During cooling, the body contracts until it reaches a minimum of the curve where, as Wright (1972) demonstrated by acoustic emission, the formation of microcracks occurs again, typically between 300 and 700°C, and the body expands again (last cooling section, Fig. 4) due to microcracking. Therefore, the specific U-shape of macroscopic dilation versus temperature curve in AT ceramics gives a clear indication of the temperature at which thermal microcracks can be considered healed and the material expands like a compact body (Bruno *et al.*, 2010). The particular shape of each thermal expansion curve in Fig. 4 is due to the microstructural differences of each material, which translate into a different length and density of microcracks as noted in the previous section.

Regarding the insulating capacity of AT materials, they can be considered good thermal insulators as a consequence of the presence of microcracks, which hinder the flow of heat via conduction. These materials present thermal conductivities, *K*, at room temperature, of around $1.5\text{--}2.5 \text{ W m}^{-1} \text{ K}^{-1}$ (Kolomeitsev *et al.*, 1981) and thermal diffusivities, *a*, of $0.3\text{--}0.6 \cdot 10^{-6} \text{ m}^2 \text{ s}^{-1}$ (one order of magnitude less than alumina). When the dependence of the thermal diffusivity with temperature is evaluated, it is observed that AT materials present an anomalous behavior (as noted previously for the coefficient of thermal expansion). Thus, the curve of thermal diffusivity versus temperature shows a hysteresis between heating and cooling, detecting a tendency of thermal diffusivity to increase with temperature (Siebenbeck *et al.*, 1976). Again, the microcracking and crack healing processes are responsible for this behavior. That is, the microstructural factors predominate over the intrinsic properties, making it impossible to extrapolate the physical properties of the single crystal to the polycrystalline material.

In addition, it should be noted that, despite the increase in diffusivity and thermal conductivity with temperature, aluminum titanate ceramics maintain an excellent thermal insulation capacity up to 1000°C (Wohlfrohm, 1991).

Fig. 5 Schematic representation of reversible microstructural changes during heating (crack healing) and cooling (crack opening). Modified from Wohlfrohm, H., 1991. Preparación por sinterización reactiva y estudio del comportamiento mecánico y térmico de materiales de titanato de aluminio (Doctoral thesis). Facultad de Ciencias. Universidad Autónoma de Madrid.

Elastic and Mechanical Behavior

Aluminum titanate ceramics are promising materials for different engineering applications because of their excellent thermal shock resistance and chemical inertness. In this sense, the guarantee of reliability has become an important requirement for AT ceramics because of their significantly low mechanical strength compared with general structural ceramics as result of the presence of microcracks along the grain boundaries. (Bruno *et al.*, 2013; Matsudaira *et al.*, 2009).

Room temperature

As a consequence of the presence of microcracks, a pure AT material with a grain size greater than the critical one for microcracking has a Young's modulus, E , ~ 10 – 20 GPa (Cleveland and Bradt, 1978), that is an order of magnitude less than the values generally found in ceramic materials. This value increases slightly, for the same grain size, in the presence of additives that enter into solid solution reducing the anisotropy of thermal expansion (Fe_2O_3 , MgO) (Maki and Suzuki, 2016; Ohya *et al.*, 2017).

With regard to hardness, AT is a relatively soft material within ceramics, with a value of 6 on the Mohs scale (such as feldspars) (Bhattacharyya and Sen, 1965) and a Vickers hardness of 5 GPa ($\text{HV} = 500$) (Dworak and Fingerle, 1987).

The mechanical strength of aluminum titanate is also a function of the grain size and the thermal history of the material. Due to the presence of microcracks, the bending strength of commercial materials usually varies between 20 and 40 MPa (Wohlfrohm, 1991). In the case of compression tests this value increased by a factor of 10–20 (Freudenberg *et al.*, 1989). It is of great interest that in these flexural and compression tests the stress-strain curves present a non-linear character, without a catastrophic failure of the material. That is, it could be treated as a behavior that is far from linear-elastic, so some authors qualify this behavior as “pseudoplastic” (Wohlfrohm, 1991) or anelasticity (Bruno *et al.*, 2013). Due to the density of microcracks, this behavior allows achievement of very high deformations for a ceramic material (up to 2% in bending and 0.8% in compression). The works by Babelot *et al.* (2011) and Chen *et al.* (2019) use the concept of “flexible” ceramic to refer to this behavior in the nonlinear stress-strain curves and propose mimicking the microstructure of natural flexible minerals like itacolumite.

The non-linear character of the stress-strain curves shows a dependence between the resistance to the propagation of a crack and the crack size. That is, there is an R-curve behavior in which the resistance to crack growth increases with its size (flaw tolerant behavior). Thus, Hamano *et al.* (1985) and Sakai and Osamu (1987) showed small increases in toughness during crack propagation in AT materials, contrary to what is observed in very brittle materials. This inelastic contribution is produced by irreversible processes such as grain bridging through the lips of the crack. Furthermore, the model of Fu and Evans (1982) analyzes the interaction of the stress field of a crack with the thermoelastic residual stresses produced by the anisotropy of thermal expansion. This model explains the strong influence of grain size on the toughness of pseudobrookites. Fine-grained materials, free of microcracks, would not present reinforcement and would be completely brittle. From a certain grain size, the formation of microcracks occurs in the process zone induced by the stress field of the main crack. This process consumes energy and produces the shielding of the main crack, which is equivalent to an increase in toughness. For grain sizes greater than the critical one, a spontaneous formation of microcracks that coalesce takes place and, consequently, a decrease in toughness occurs. Fu and Evans (1982) estimated that this microcracking reinforcement develops from a grain size of approximately 0.4 times the critical grain size for spontaneous microcracking.

Effect of temperature

Uncommon in a ceramic material is the significant increase in Young's modulus with temperature (Freudenberg *et al.*, 1989; Ohya *et al.*, 1988). Young's modulus is maximum (around three times the value at room temperature) at $\sim 900^\circ\text{C}$. There is also a hysteresis between heating and cooling, indicating that the same processes of recombination (crack healing) and formation of microcracks that determine thermal expansion are also responsible for the variation of Young's modulus with temperature.

In a similar way to what happens with Young's modulus, strength increases with temperature up to approximately 1200°C (Freudenberg *et al.*, 1989; Ohya *et al.*, 1988; Kolomeitsev *et al.*, 1981; Kim *et al.*, 2014; Papitha *et al.*, 2014).

Table 3 Decomposition ratio (wt%) of AT in alumina-aluminum titanate monolithic composites treated at 900, 1000 and 1150°C for 4 h with heating and cooling rates of 5°C min⁻¹

Annealing treatment – 4 h	Specimens sintered at 1450°C – 2 h			Specimens sintered at 1550°C – 3 h		
	900°C	1000°C	1150°C	900°C	1000°C	1150°C
Alumina + 10 wt%AT	Traces	9	100	Traces	7	100
Alumina + 30 wt%AT	Traces	21	100	Traces	22	100
Alumina + 40 wt%AT	Traces	22	100	Traces	21	100

Thermal Stability

Aluminum titanate is classically produced by heating a combination of alumina and titania up to a temperature above 1350°C at atmospheric pressure. However, pure synthesized AT is thermally unstable below 1280°C. Therefore, it tends to decompose, through a eutectoid reaction, into alumina and titania during cooling from sintering treatments, which would render the material useless for industrial applications. However, at temperatures below 800–900°C there is a kinetic inhibition of this decomposition (Buscaglia and Nanni, 1998).

Different authors have reviewed and analyzed the main strategies to control or delay the AT thermal decomposition (Wohlfromm, 1991; Barrios de Arenas, 2012; Pratapa *et al.*, 2011). In the first place, as has been commented on throughout this chapter, there is a dependence between the degree of thermal stability of the material and its history throughout processing: forming pressure, atmosphere and temperature of the thermal treatment and, on the final grain size of the material (Wohlfromm, 1991; Naghizadeh *et al.*, 2009). Secondly, there is a general agreement on improving AT stability through the formation of solid solutions by doping with oxide additives such as magnesium oxide (MgO) and ferric oxide (Fe₂O₃) which are isomorphous with the pseudobrookite structures, and thus form solid solutions with AT (Buscaglia *et al.*, 1996a,c; Ishitsuka *et al.*, 1987; Korim, 2009).

This thermodynamic stabilization is related to the material's decreased decomposition temperature during cooling (MgTi₂O₅ and Fe₂TiO₅) decompose below 700 and 565°C, whereas AT decomposes at 1280°C. This is explained by the smaller differences between the ionic radii of Fe, Mg and Ti, which produces a lower degree of distortion of the octahedra that form the structure. The improved stabilization in the solid solutions is also due to increased entropy caused by cation mixing disorder (Kim and Gauckler, 2012). Among other possible stabilizing oxides, SiO₂ has been studied to a greater extent, with limited solubility in AT (Ishitsuka *et al.*, 1987). An important note in mixing additives is that they should not significantly decrease the aluminum titanate properties. Small additions (≤ 3–5 wt%) are usually incorporated with the aim of forming aluminum titanate solid solutions.

In the case of alumina-aluminum titanate composite materials with improved toughness presented in the following section, a higher decomposition has been determined than in single-phase AT materials, due to the action of the alumina particles as nucleation points for the decomposition reaction (Uribe, 2001). In the literature, maximum values of decomposition rate are reported at temperatures between 1000°C and 1200°C, with peak values between 1100°C and 1150°C (Buscaglia and Nanni, 1998; Uribe, 2001), while below 800–900°C the materials can be considered stable. Therefore, a study of the decomposition in the materials is necessary in order to determine their maximum application time and temperature. Based on these observations, the AT decomposition study was carried out in samples of alumina-aluminum titanate composite monoliths (with volumetric proportions of AT particles in the range 10–40 vol%) treated at 900, 1000 and 1150°C for 4 h (Table 3). It was observed that in the samples treated at 900°C there was no decomposition, while in the samples treated at 1150°C the decomposition was total in 4 h. For the treatment at 1000°C, moderate decomposition (~ 10–20 wt%) is shown.

These values show a good agreement with results obtained by other authors (Uribe, 2001) where a decomposition of 15 wt% has been found in alumina materials with 10 vol% of aluminum titanate, treated at 1000°C for 4 h.

AT-Based Materials

As discussed above, microcracked aluminum titanate materials present desirable properties; however, their use in critical structural applications is limited due to lack of strength. The typical ceramic processing approach of strengthening a material by reducing its grain size in order to limit microcracking on cooling would succeed in strengthening aluminum titanate. However, it is inherently accompanied by an undesirable increase in thermal expansion, thermal conductivity and Young's modulus. Moreover, the control of grain growth in reaction sintered AT materials is complicated because of the specific characteristics of the reaction process.

Solid Solutions in Aluminum Titanate

Efforts have been devoted to decreasing the thermal expansion anisotropy of the aluminum titanate crystals by doping to form solid solutions and increase strength values (Thomas and Stevens, 1989b; Maki and Suzuki, 2016; Ishitsuka *et al.*, 1987; Korim, 2009; Guedes-Silva *et al.*, 2016; Rezaie *et al.*, 2009).

Recently, as an example, [Ohya et al. \(2017\)](#) have investigated the co-doping of MgO with Y_2O_3 , La_2O_3 and Nb_2O_5 to fabricate aluminum titanate ceramics that possess both low thermal expansion coefficients and excellent mechanical properties. The best results were found for Mg-Y co-doping. In this respect, a material with average thermal expansion between room temperature and 1000°C similar to that of the undoped material ($\sim 3 \times 10^{-6}\text{K}^{-1}$) and strength ~ 60 MPa was developed by sintering at intermediate temperature (1450°C). Increasing the sintering temperature to 1500°C significantly decreased the thermal expansion coefficient ($\sim 0.7 \times 10^{-6}\text{K}^{-1}$) but was associated with a sharp decrease in strength (~ 17 MPa).

Strengthened AT Materials With Enhanced Structural Integrity

Different ceramic composites with aluminum titanate as one of the major phases have been proposed ([Basnet et al., 2017](#); [Luo et al., 2015](#); [Xu et al., 2015](#)). The aim is to exploit the excellent resistance to thermal shock of aluminum titanate in applications such as thermal barrier coatings, exhaust filter components for diesel engines and high temperature ceramic substrates with improved mechanical properties. Such approach has been successful for dense AT ([Violini et al., 2018](#); [Parker, 1990](#)) or porous materials containing zirconium titanate ([Sarkar et al., 2015](#)), which present increased structural integrity while maintaining low, or even negative, thermal expansion coefficients. In the same way, [Zhao et al. \(2016\)](#) reported strengthened aluminum titanate reinforced by calcium dialuminate with thermal expansion similar to that of the matrix. Porous aluminum titanate materials with mullite additions up to 50 vol% ([Sarkar et al., 2016](#); [Xu et al., 2015](#)) also present enhanced structural integrity even though they experience increased thermal expansion especially for the highest mullite contents.

Materials Reinforced by Aluminum Titanate

An important field of research during the last years has been that of developing composites with aluminum titanate as second phase, in order to improve the mechanical behavior of the matrix by manipulating the thermal stresses associated with the thermal expansion behavior of this phase. It is well known that thermal expansion mismatch between the matrix and the dispersed phases might lead to different toughening mechanisms, i.e., crack deflection, crack branching, crack bridging and microcracking. Un-cracked composites based on this approach present thermal expansion behavior similar to that of the matrices, with lower average coefficients as function of the composition (e.g., [Uribe and Baudín, 2003](#)) and the microcracked ones present thermal expansion hysteresis associated with the presence of microcracks ([de Portu et al., 2006](#)).

[Morishima et al. \(1986\)](#) and [Yano et al. \(1992\)](#) reported that only relatively large additions of AT (> 63 vol%) led to significant increases in the thermal shock resistance of mullite and that such additions were associated with sharp strength decreases due to microcracking. [Kucuk and Boyraz \(2019\)](#) did not find any beneficial effect of aluminum titanate on the mechanical behavior of yttria stabilized zirconia.

The most investigated system is that of alumina-aluminum titanate. In this system, materials present extremely different mechanical behaviors as a function of the length scale in the microstructure because such scale determines the main toughening mechanisms ([Park et al., 2003](#)). As an example, in fine grained materials of alumina with 10 vol% of aluminum titanate, microcracking was identified as the main toughening mechanism in alumina matrices with AT nanoparticles at the grain boundaries ([Bueno et al., 2008](#)) and crack bridging for those matrices with a uniform dispersion of micrometric AT particles ([Uribe and Baudín, 2003](#)). The same conclusions were reached later by [Sobhani et al. \(2016\)](#) for materials with higher content of AT.

[Wang et al.](#) have investigated a series of dense ([Wang et al., 2009](#); [Yang et al., 2009a](#); [Wang et al., 2005](#)) and porous ([Yang et al., 2009b](#)) alumina-aluminum titanate composites with micro and nano-scale microstructures. Such composites presented relatively high strength, especially the nanostructured composite, with 426 MPa compared to 222 MPa for the composite with micro-scale microstructure, and both showed good wear resistance ([Sharma and Dogan, 2019](#); [Wang et al., 2005, 2009](#)), especially the one with the micro-scale microstructure ([Wang et al., 2009](#)).

Characteristic examples of monolithic materials and laminates developed in the alumina-aluminum titanate system are described in the sections which follow. Colloidal shaping methods allow the fabrication of homogeneous monolithic materials with a wide range of microstructures ([Bueno et al., 2004](#)) and laminated materials consisting of layers of very different microstructures ([Bueno and Baudín, 2006](#); [Bueno et al., 2011](#)).

Monolithic Alumina-Aluminum Titanate Composites

Due to the thermal expansion mismatch between aluminum titanate ([Taylor, 1987](#)) and alumina ($\alpha_{a25-1000^\circ\text{C}} = 8.4 \cdot 10^{-6}\text{K}^{-1}$, $\alpha_{c25-1000^\circ\text{C}} = 9.2 \cdot 10^{-6}\text{K}^{-1}$) ([Taylor, 1984](#)) high residual stresses between the grains can arise in alumina-AT composite materials during cooling from the sintering temperature, depending on their crystallographic orientation. Specifically, in the orientations in which the aluminum titanate grains present a lower coefficient of expansion than the alumina grains, they are subjected to compressive stresses and, as a consequence, can act as crack bridging sites during fracture ([Padture et al., 1993a](#); [Runyan and Bennison, 1991](#)). The extreme local stresses that develop in these compounds can also generate microcracks during cooling or during material loading and, therefore, the grain size of the materials has to be controlled below the critical size so that generalized failure does not occur.

This critical size has been evaluated ([Uribe and Baudín, 2003](#)) by means of a simple energy approximation, at $6.4 \mu\text{m}$, for the formation of circumferential cracks around the tensile grains of aluminum titanate, and at $2.2 \mu\text{m}$ for the formation of radial

cracks from the grains of aluminum titanate subjected to compression. These values are in agreement with the experimental results of Padture *et al.* (1993a,b). The level of cracking depends on the number of grains that contribute and, therefore, their size and the volume fraction of aluminum titanate. Thus, in compounds with AT contents of 10–40 vol%, a gradual decrease in fracture stress is observed from ~ 300 MPa, for average grain sizes of $2\text{ }\mu\text{m}$, to a drastic drop ($\sim 20\text{--}30$ MPa) for average grain sizes of the order of $4\text{--}7\text{ }\mu\text{m}$ (depending on the volumetric content of AT) (Padture *et al.*, 1993b).

In addition to microcracking and crack bridging as toughening mechanisms in alumina-AT composites, crack branching and crack deflection are also identified in the alumina materials with 30 and 40 vol% of AT described below. These materials were manufactured by a colloidal route (slip casting) from aqueous alumina and titania suspensions and sintered with 2 h dwell at 1450°C and 3 h dwell at 1550°C . In all these composites the mean sizes of the aluminum titanate grains (Table 4) were in the order of or higher than the critical value, thus explaining the presence of microcracks in the as sintered state (Fig. 6(a)) that propagates preferentially along grain boundaries and gives rise to non-linear load-displacement curves (Fig. 6(b)).

Table 4 Main properties of Alumina-30 vol%AT and Alumina-40 vol%AT ceramic composites sintered at 1450°C and 1550°C . G: grain size, $\alpha_{25-850^\circ\text{C}}$: average thermal expansion coefficient between 25 and 850°C , σ_f : 3-point bending strength, γ_{WOF} : work of fracture. A: Alumina, AT: Aluminum titanate; sd: standard deviation

	G_A (sd) μm	G_{AT} (sd) μm	$\alpha_{25-850^\circ\text{C}}$ (sd) 10^{-6}K^{-1}	σ_f (sd) MPa	γ_{WOF} (sd) J/m^2
1450°C					
Alumina + 30 wt%AT	2.3 (0.2)	2.2 (0.2)	5.6 (0.4)	94 (10)	57.4 (3.9)

Fig. 6 Characteristic microstructural and fracture features of alumina-30 vol%AT and alumina-40 vol%AT composites sintered at 1450 and 1550°C . (a) As sintered microstructure (b) Non-linear load-displacement curve of notched specimens (c) Fracture surface displaying numerous crack deflections (d) Crack branching detail in the crack profile of notched specimens.

The macroscopic features of the fracture surfaces and crack path (Fig. 6(c) and (d)) are conditioned by the relatively long cracks already presented in the as-sintered materials. The main crack diverts and branches by the interaction with the pre-existing cracks leading to crack profiles like that shown in Fig. 6(d), where portions of material not fractured remained trapped along the wake of the propagating crack.

Thermomechanical characterization of these alumina-AT materials in Table 4 shows values of the coefficient of thermal expansion and of the work of fracture in the order described for pure AT materials stabilized by doping (Ohya *et al.*, 2017) but with superior strength values.

Structural Layered Composites

The development of laminated ceramic materials emerged as a design strategy to minimize the inherent brittleness and unreliability of ceramic materials during fracture. Some of the designs used for ceramic laminates are those that introduce flaw-tolerant inner layers and have strong interfaces between them and the outer layers of higher strength (Chan, 1997; Clegg, 1998; Lawn *et al.*, 2002). Another group of designed ceramic laminates is that of layers joined by weak interfaces to initiate crack deflection (Chan, 1997; Clegg, 1998; Tomaszewski *et al.*, 2007; Zhang *et al.*, 2004) to reach high toughness values. Such materials present graceful fracture under loads perpendicular to the layers due to their high capability for crack deflection and delamination along the weak interfaces.

Bueno and colleagues (Bueno *et al.*, 2005; Bueno and Baudín, 2006, 2007, 2009) have developed alumina-aluminum titanate based laminates designed to combine high crack deflection capability with strong interfaces. They consisted of relatively stiff and brittle external layers with microcracked internal layers, with moderate AT contents, to produce multiple crack deflection and/or branching. The most important difference between these laminated structures and other laminates with high capability for crack

Fig. 7 Characteristic fracture features of alumina-aluminum titanate based laminates. Thin internal layers in the micrographs are formed by highly microcracked alumina-50 vol%AT composite. (a) Detail of fracture surface in an internal layer (b) Graceful failure in load-displacement curve of notched specimens (c) Crack profile in a notched specimen showing main crack deflection by interacting with microcracks in the internal layers. (d) Crack profile of a notched specimen showing branching of the main propagating crack by interacting with microcracks in the internal layers.

deflection is that in these ones delamination occurred at the microstructural level and, thus, delamination lengths were limited and delamination did not lead to the loss of structural integrity.

The behavior of laminated structures with relatively highly microcracked thin internal layers containing 50 vol% of AT is now presented. These laminates had stiff and brittle surface layers of alumina or alumina + 10 vol% AT and were sintered for 2 h dwell at 1450°C. Characteristic fracture features of the tested specimens are shown in Fig. 7. In all specimens, the internal A50 layers were well defined and showed multiple fracture planes (Fig. 7(a)). It is clear from the aspect of the A50 layers in the fracture surfaces that the main crack experienced multiple deflections and branching due to its interaction with the microstructure of the weak and thin internal layers. Such processes led to crack arrest and re-initiation at the internal thin layers and thus to the graceful failure presented by the load-displacement curves (Fig. 7(b)) as can also be inferred from the crack profile observed in the lateral surfaces (Fig. 7(c) and (d)). Work of fracture values of these laminated structures were in the order of 100–120 J m⁻², superior to those described for alumina-AT monoliths in Table 4.

Technological Interest

Summarizing the main considerations from the previous sections, aluminum titanate materials have high melting point, chemical inertness and excellent resistance to thermal shock due to their low coefficient of thermal expansion. Furthermore, the presence of microcracks also leads to low thermal conductivity. Therefore, one of the main uses of these materials is aimed at applications where thermal insulation is required (Mandal *et al.*, 2017; Stingl *et al.*, 1986). However, such applications are limited because microcracking is associated to strength values an order of magnitude lower than the typical values of ceramic materials (~15–20 MPa). Aluminum titanate is also important for ceramic industry due to its good chemical resistance and, in this way, aluminum titanate is a suitable material for various technological applications such as foundry parts or catalytic converters for motor vehicles (Barrios de Arenas, 2012).

Refractories

Aluminum titanate is commercially considered a specialized material for extreme temperature conditions and found mostly in the non-ferrous molten metal industry, especially in aluminum foundries. Some specific applications in this field are: nozzles, casting molds, crucibles, spacers, mold joints, flow rods, retainer rings, riser tubes, feeders or dosing tubes among many other components or devices for the treatment of molten metals (Ceramtec®). In addition, the poor wettability of aluminum titanate with molten metals is another of the properties that makes it ideal for use in foundry technology and metallurgical melting (Ceramtec®, Cumi®, Kyocera®). On the other hand, it must also be added to this exceptional behavior that the thermal conductivity is in the range 1–2 W m K⁻¹ for refractory ceramics based on AT. This low thermal conductivity saves energy, giving rise to energy-efficient processes, increased process reliability, reduced freeze-offs and improved yield levels (Cumi®). It is also remarkable that the outstanding chemical and abrasive resistance of AT ensure high melt purity and, thus, prevents metal adhesion, simplifies cleaning, increases service life, does not contaminate the melt and enhances product quality and plant efficiency. When compared to competing materials like calcium silicate and fused silica, components manufactured using aluminum titanate have significantly longer service life (Ceramtec®).

To all these characteristics it must also be added that microcrack healing during heating AT ceramics increases strength with increase in temperature, which further favors, if required, the high chemical resistance of these materials.

Advanced Engineering Applications

AT also demonstrates great versatility for specific engineering applications. In particular, the exceptional thermal behavior of AT makes it a good option for substrates in catalytic converters for motors, spacing rings of catalytic reactors, vehicle emissions control, diesel particulate filters, high-temperature flue gas filtration supports and thermal insulation liners (Li *et al.*, 1995; Kim, 2010; Adler and Petasch, 2013).

In particular, several investigations have been undertaken regarding the use of AT materials for the development of diesel particulate filters (DPF) (Brodnik and Faber, 2019; Chen *et al.*, 2020; Kim, 2010; Millo *et al.*, 2015; Papitha *et al.*, 2014). Since 2009 wall flow DPFs have been adopted for all European passenger cars, in order to comply with the PM (Particulate Matter) EU5 emissions limits. Silicon carbide and cordierite filters are commonly used for this application, but dense AT with engineered porosity is an interesting ceramic material for DPF due to its very low thermal expansion coefficient and thermal shock resistance in combination with high refractoriness and melting point. Main results showed that aluminum titanate and cordierite, compared to silicon carbide, can give significant advantages in terms of price, thermal expansion and in reducing the temperature loss through the DPF (Kim, 2010). However, increased regeneration frequency of AT and cordierite leads to significant penalties in terms of fuel consumption and oil life compared to silicon carbide. However, this gap could be partially overcome by adopting specific regeneration strategies (Millo *et al.*, 2015).

Another new application for aluminum titanate is its use in solid oxide fuel cells (SOFC) (Welander *et al.*, 2019, 2018; McCleary and Amendola, 2018; Law and Sofie, 2011; Hunt *et al.*, 2018; Welander *et al.*, 2018; McCleary and Amendola, 2018; Law

and Sofie, 2011; Hunt *et al.*, 2018). Aluminum titanate has been incorporated in the standard SOFC anode, the Ni-YSZ cermet, in order to prevent anode degradation and improve mechanical properties and cell performance.

Other minor applications refer to the use of AT as a biomaterial for bone repair (Kalita and Somani, 2010), as a catalyst (Almerindo *et al.*, 2016) or even as a photoactive material (Trung *et al.*, 2019).

Summary

In general, AT materials have to compromise between demands for a low macroscopic thermal expansion coefficient and high strength and, thus, in spite of the fact that microcracking would limit the strength, it has a positive effect of decreasing thermal expansion coefficient. In this way AT materials become especially resilient to thermal shock stresses.

Different processing and design strategies are being evaluated to increase the strength of AT materials without sacrificing the properties that make aluminum titanate unique. These possibilities range from the development of solid solutions to the formation of flaw-tolerant laminated structures, including the design of composites with other ceramic compounds.

This improvement in properties increases the chances of success of AT materials for advanced engineering applications that are already being investigated, apart from their traditional use as a refractory material.

Introduction

Zirconia (Zirconium oxide, ZrO_2), the oxide of zirconium metal, occurs as a natural mineral and is formed in igneous rocks such as schists, gneiss, granites, and syenites. Zirconia was first identified by the German chemist Martin Heinrich in 1789 (cited by [Klaproth, 1958](#)) as a reaction product of heating zirconium. In 1892, a more abundant source was discovered in the mineral baddeleyite (80%–98% of zirconia) (cited by [Audley, 1917](#)) from which a relatively pure zirconia can be prepared. Baddeleyite contains small amounts of silica and iron as impurities. In this form it is concentrated in the tailings of the uranium and copper deposits found at Palabora, South Africa. All deposits of zirconia also contain a small percentage of hafnium, separation of which can only be achieved by sophisticated chemical processing such as occurs in ion exchange columns. Other main sources of the oxide are in Northern Russia. Zirconia is also extensively recovered from zircon (the zirconium orthosilicate: ZrSiO_4), which is found in several areas of the world as beach sand. The relatively pure oxide, containing hafnia (<2%) is found in nature as comparatively large particles (>1 mm) of monoclinic phase, which has been formed over a long period of time by hydrothermal dissolution and precipitation.

The monoclinic form is thermodynamically stable at room temperature but transforms reversibly to the tetragonal crystallographic system on heating above 1170°C, the transformation being accompanied by a decrease in volume of approximately 4%–5%. Conversely, the transformation from tetragonal to monoclinic on cooling shows a volume increase, occurs at high speed and is used to develop extraordinary properties in zirconia-based engineering ceramics. The crystal structures are unusual in that the structure becomes more symmetric on heating; thus, the monoclinic form (space group $P2_1/c$) first transforms to the tetragonal form (space group $P4_2/nmc$) and at 2370°C to the cubic fluorite phase (space group $Fm\bar{3}m$) ([Fig. 1](#)). Intermediate between the tetragonal and the cubic crystal, several high-pressure orthorhombic forms have also been detected ([Bouvier et al., 2000](#)). Use of pure zirconia in applications is not feasible due to the large volume change of the tetragonal to monoclinic phase transformation that leads to the disintegration of sintered parts during cooling. The problem has been alleviated by alloying zirconia with other oxides that stabilize tetragonal and/or cubic phases down to room temperature, thus preventing the tetragonal to monoclinic transformation. Since this discovery, many conferences and books have been devoted to the science and technology of zirconia ([Heuer and Hobbs, 1981](#); [Claussen et al., 1984](#); [Somiya et al., 1988](#); [Badwal et al., 1993](#)).

Fig. 1 The crystal structures of zirconia showing the effect of temperature, stabilizer addition and temperature hysteresis for transformations. Adapted from Ricca, C., Ringued, A., Cassir, M., Adamo, C., Labat, F., 2015. A comprehensive DFT investigation of bulk and low-index surfaces of ZrO_2 polymorphs. *J. Comput. Chem.* 36, 9–21.

The relationships between the crystallographic phases are best shown diagrammatically, where it can be seen that the symmetry increases with temperature and stabilizer content (Fig. 1).

The higher temperature phases may thus be stabilized by the addition into solid solution of specific cubic oxides. Additives, also known as stabilizers, such as CaO, MgO, Y_2O_3 and CeO_2 , in which the cations have a similar ionic radius to Zr and sufficient solid solubility, will, when incorporated into the monoclinic phase, first stabilize the tetragonal form and with further addition, the cubic phase. There are many elements in the periodic table which satisfy the radius criterion, but only a few have sufficient solid solubility so that the most efficient stabilizers are limited to several rare-earth elements. Factors other than the simple radius ratio which might contribute to cubic stability include the development of increased covalent bonding and the generation of sufficient oxygen vacancies to accommodate eightfold coordination of the oxygen ion sites.

Tetragonal-Monoclinic Phase Transformation

The tetragonal phase of zirconia exists over a temperature range. On cooling below 950°C , it transforms to the monoclinic phase. The transformation occurs by a diffusionless shear process at high speed (near sonic velocity), with a thermal hysteresis developed between the heating and cooling cycles (Fig. 2). The transformation is akin to that of the martensitic transformation which occurs when steel is quenched from its austenitic phase. In addition, it has been demonstrated that the transformation is dependent on the particle size of the components, finer particles transforming at a lower temperature than coarser particles.

The martensitic nature of the transformation has been confirmed by transmission electron microscopy when extensive shear in the form of twin generation has been observed (Leriché, 1986) (Fig. 3). In zirconia, three different crystallographic correspondences exist

Fig. 2 Temperature hysteresis for the monoclinic-tetragonal transformation of pure zirconia.

Fig. 3 Transmission electron micrograph in dark field, showing transformed (tetragonal - monoclinic) zirconia particle. The transformed phase (zirconia particle in a mullite matrix) consists of narrow twins, indicative of a martensitic shear type transformation. Reproduced from Leriché, A., 1986. Influence of Mullite-Zirconia Composites Processing Parameters on Their Microstructure. (Ph.D. thesis). Belgium: University of Mons. (in French).

between the parent (tetragonal) and the product (monoclinic) phase, called ABC, BCA and CAB, which imply that the lattice parameters of the tetragonal phase (a_t , b_t , c_t) change into (a_m , b_m , c_m), (b_m , c_m , a_m) and (c_m , a_m , b_m), respectively. Each of these lattice correspondences may occur along two different habit planes, leading to six different configurations. For each, the volume change or dilatation component of transformation strain is around 5% and the shear strain is around 16%, which is 3 or 4 times larger than the dilatational component (Kelly and Francis Rose, 2002; Chevalier *et al.*, 2009).

A thermodynamic analysis of the nucleation and growth of the monoclinic martensite phase has been made to explain the effect of particle size on phase stability. A key issue has been that of nucleation of the martensite platelets and evidence for both homogeneous and heterogeneous nucleation is available. For the polycrystalline ceramic systems of technological interest, the importance of stress raising sites and of strain energy is well established. The availability of a martensitic transformation in zirconia has allowed the development of a range of transformation toughened ceramics, which not only improve the toughness of the host but also allow remarkable increases in strength. Furthermore, the process also leads to the development of stress-induced compressive surface stresses which for the first time allow ceramics to become more tolerant to surface flaws.

These toughening phenomena will be described below.

Stress-Induced Transformation Toughening

When heated above $\sim 1170^\circ\text{C}$, monoclinic zirconia transforms to the tetragonal phase. On cooling, the tetragonal-monoclinic transformation should take place with a significant volume increase. However, if the ZrO_2 is in the form of finely divided particles (below a critical size of ~ 20 nm), or has a constraining pressure exerted on it by the matrix, then the zirconia particle can be retained in the tetragonal state as a metastable phase. Such metastable tetragonal crystals can be introduced into suitable matrix materials such as alumina during the initial stages of fabrication or they are formed in-situ from cubic solid solutions by applying secondary heat treatment after sintering, as in the case of Mg-PSZ (see below). As previously mentioned, the tetragonal phase can also be retained at room temperature in zirconia ceramics by adding stabilizing oxides, such as yttria (Y_2O_3) or ceria (CeO_2). Tetragonal zirconia polycrystalline (TZP) materials exhibit nearly 100% tetragonal phase and are often designated with a prefix to denote the stabilizing cation and its content, for example 3Y-TZP represents a 3 mol% Y_2O_3 stabilized zirconia.

Fig. 4 Diagrammatic representation of the transformation toughening process in the region of an opening crack tip (a) in polycrystalline TZP zirconia and (b) in ceramics containing tetragonal particles. Fig. 5 Diagram showing how the presence of microcracking around a spontaneously transformed ZrO_2 particle has caused bifurcation and deflection of a growing critical crack, thereby toughening the host material.

The martensitic tetragonal to monoclinic transformation can be induced by cooling, by external loading and in some ceramics spontaneously if they are put in contact with water. The stress-induced transformation enhances the toughness of zirconia ceramics. In TZP, the transformation toughening process occurs when metastable retained tetragonal grains transform to their monoclinic form in the tensile stress field created around a propagating crack (Fig. 4(a)). In the case of tetragonal particles dispersed in a matrix, if a crack is made to extend under a stress, then tensile stresses are generated around and ahead of the crack tip. When the stresses are large enough and released on the metastable tetragonal zirconia particles, the particles transform to the monoclinic phase (Fig. 4(b)). The tetragonal to monoclinic transformation occurs at a given stress (critical transformation stress) and implies a volume increase, typically 4%–5%. The volume expansion generates large compressive stresses in the process zone around the crack tip. This reduces the local crack tip stress intensity and hence the driving force for crack propagation, so increasing the effective toughness of the ceramic. A critical size range exists within which the metastable tetragonal particles can be induced to transform. Below this range, the particles cannot transform and above it they transform spontaneously. The size range depends on factors such as the degree of matrix constraint, the degree of substitutional stabilization, and the shape and distribution of the zirconia particles.

Microcrack Toughening

Microcracks can be readily introduced into a ceramic matrix (cubic zirconia or another ceramic such as alumina) by the incorporation of the transformable tetragonal phase. Spontaneous transformation on cooling through the transformation temperature results in a large volume increase (4%) which cannot be accommodated by elastic strains and consequently results in the development of microcracks (Fig. 5). These can be used to deflect a primary crack enhancing the toughness and/or the thermal shock resistance in the process. Provided the microcracks are small compared with the primary crack, then they would have a minimal effect on the fracture strength. Optimum conditions arise when the microcracks are small enough to deflect the primary crack but are too small or too few to link up and increase the effective length of the critical crack.

Similarly, the maximum toughness is reached when the number of cracks is at a maximum such that deflection occurs but not a linking up of adjacent microcracks. The situation is generally obtained with 10%–15% of the material in the form of transformed monoclinic particles.

Phase Relationships

Extensive literature exists on the phase equilibria of zirconia. Many binary and ternary systems have been investigated in detail, in particular, $\text{ZrO}_2\text{-MgO}$, $\text{ZrO}_2\text{-CaO}$, $\text{ZrO}_2\text{-Y}_2\text{O}_3$, and $\text{ZrO}_2\text{-rare-earth oxide(s)}$. Substitution is dependent on compatible ionic size and in addition the electrical neutrality must be maintained in conjunction with the substitution. Thus, ions having a different valency must be compensated for with an appropriate number of anion or cation vacant sites in the modified crystal. The condition for Mg^{2+} substitution for Zr^{4+} is:

Where Mg_{Zr}'' represents a zirconium site occupied by magnesium (double-charged negatively), O_0 represents an oxygen site occupied by oxygen (neutral) and $\text{V}_{\text{O}}^{\bullet\bullet}$ a vacancy on an oxygen site (double-charged positively).

Stabilization is considered to be helped by the creation of oxygen vacancies which effect a distortion of the tetragonal and monoclinic unit cells to the more symmetric cubic symmetry.

The high melting points and low cation mobility of the constituents constrain the development of equilibrium conditions, which makes for experimental difficulties, notably the extensive time required for accurate determination of the precise limit of the phase fields, particularly those at medium and low temperatures.

It is noticeable that the addition of the second component has the effect of reducing the transformation temperature of the monoclinic transformation. A further feature of interest is the increase with temperature of the compositional range of the tetragonal phase field, which will as a consequence allow heat treatment and phase separation, subsequent to a primary sintering cycle, in the process enhancing the properties of the sintered ceramic.

ZrO₂-MgO

The ZrO₂-MgO system has been used extensively and the phase diagram given in Fig. 6 is widely accepted. Of particular interest to technological applications is the presence of a region above 1400°C consisting of a mixed cubic and tetragonal phase. At lower temperature in the range 1200–1400°C, the monoclinic phase is stable, by virtue of a decomposition reaction, when the cubic phase breaks down to form the tetragonal phase and free MgO.

Manipulation of this region of the phase diagram has allowed the development of strong tough engineering ceramics designated as partially stabilized zirconia (PSZ) based on the principle of transformation toughening. The structure developed consists of large (> 50 μm) grains of cubic matrix containing a uniform dispersion of lenticular tetragonal phase (Fig. 7). The properties of Mg-PSZ are summarized in Table 1.

Generally, commercial ZrO₂-MgO materials are produced within a limited composition range of 8–10 mol% MgO. The first commercial zirconia-based product appeared in 1928 and was a MgO-stabilized ZrO₂ crucible for metal melts. Today, magnesia-stabilized zirconia is available both partially and fully stabilized for applications including structural ceramics for turbine blades, anti-ballistic and armor ceramics and ionically conductive uses.

ZrO₂-Y₂O₃

Although Y₂O₃ and ZrO₂ have different space groups, the arrangement of the ions is similar with only a small shift in the atomic positions. Thus, the solubility limit of Y₂O₃ in both the monoclinic and tetragonal phases is relatively high, giving extensive tetragonal and cubic solid solution phase fields in the phase diagram. The extended range of the tetragonal phase field has

Fig. 6 Equilibrium phase diagram for ZrO₂-MgO. Adapted from Grain, C., 1967. Phase relations in the ZrO₂-MgO system. *J. Am. Ceram. Soc.* 50, 6, 288–290.

Table 1 Comparison of zirconia ceramic properties

Ceramic	Toughness ($\text{MPa m}^{1/2}$)	Flexural strength (MPa)	Weibull modulus	Grain size (μm)	Hardness (GPa)
Mg-PSZ	5	600	–	50	12
Y-TZP	7–12	1000–1200	8	0.3	12–14
Ce-TZP	15–20	400–600	20	2–3	8–10

**Fig. 8** Equilibrium phase diagrams for $\text{ZrO}_2\text{-Y}_2\text{O}_3$. Reproduced from Lakiza, S., Fabrichnaya, O., Zinkevich, M., Aldinger, F., 2006. On the phase relations in the $\text{ZrO}_2\text{-YO}_{1.5}\text{-AlO}_{1.5}$ System. *J. Alloy. Compd.* 420, 237–245.

considerable importance in the transformation toughening of commercial ceramics. The equilibrium phase diagram $\text{ZrO}_2\text{-YO}_{1.5}$ presented in Fig. 8 shows that from a thermodynamic point of view, the tetragonal phase should not exist at low temperature even in the presence of yttria: a mix of monoclinic and cubic solid solutions are expected. However, from a kinetic point of view, since at the eutectoid temperature (near 1000°C) the diffusion of yttrium ions in the tetragonal structure is very low, it is very easy to retain the tetragonal phase until room temperature. To give a more precise idea, the time required for Y^{3+} to migrate 150 nm would be 10^7 seconds (several months!) (Kilo *et al.*, 2000).

Thus, the addition of yttria to zirconia has two significant effects. It extends the range of the tetragonal phase field and also has the effect of lowering the temperature at which the tetragonal-monoclinic transformation takes place. Moreover, the Zr^{4+} substitution by a trivalent cation generates oxygen vacancies for maintaining the charge neutrality. Oxygen vacancies are responsible for the phenomenon of Low Temperature Degradation (LTD) or aging in the presence of moisture. This enables the fabrication of dense zirconia polycrystalline ceramics consisting of nearly 100% tetragonal phase (TZP) (Fig. 9). Typically, at 2.5–3 mol% Y_2O_3 the material produced is stable at room temperature providing it has a sufficiently small grain size. Materials based on these compositions are fabricated commercially and have found widespread use in markets involving cutting and wear applications, where the materials have proved superior to any available alternative metal or ceramic. From early 1990s, 3Y-TZP was used in orthopedics for the fabrication of femoral heads for total hip arthroplasty until 2001, when more than 400 failures of zirconia heads were reported, associated with an accelerated aging issue. Since then, Y-TZP ceramics are used in the dental field for manufacturing implants, abutments, crowns and bridges. Due to the phase transformation toughening mechanism, 3Y-TZP ceramics exhibit outstanding mechanical properties (i.e., strength >1000 MPa and toughness ~ 6 $\text{MPa m}^{1/2}$).

Fig. 9 Transmission electron micrograph showing the fine grained metastable tetragonal phase of TZP, stabilized with yttria. Reproduced from Stevens, R., 1986. An Introduction to Zirconia, second ed. London, England: Magnesium Elektron Ltd. (Magnesium Elektron Publication No 113).

Fig. 10 Equilibrium phase diagrams for $\text{ZrO}_2\text{-CeO}_2$. Adapted from Huang, S., Li, L., Vleugels, J., Wang, P., Van der Biest, O., 2003. Thermodynamic prediction of the non stoichiometric phase $\text{Zr}_{11-x}\text{Ce}_x\text{O}_{2-x}$ in the $\text{ZrO}_2\text{-CeO}_{1.5}\text{-CeO}_2$ system. J. Eur. Ceram. Soc. 23 (1), 99–106.

$\text{ZrO}_2\text{-CeO}_2$

In the case of ceria stabilization, the Zr^{4+} substitution by an isovalent cation does not generate oxygen vacancies since the neutrality of the crystal is not compromised. However, the number of oxygen atoms surrounding the Zr^{4+} will be reduced due to the longer chemical bond for Ce-O than for Zr-O leading to tetragonal stabilization. For stabilizing zirconia with ceria, relatively high quantities of this oxide are necessary, at least 10 mol% as illustrated in Fig. 10. As cerium presents 2 oxidation states (+2 and +4), only 6 mol% will be necessary to stabilize the tetragonal phase in the case of sintering materials under reducing atmosphere, favorable to Ce^{2+} (Zhu, 1994).

Contrary to 3Y-TZP ceramics which exhibits relatively moderate toughness ($\sim 6 \text{ MPa m}^{1/2}$) but impressive strength ($> 1000 \text{ MPa}$), Ce-TZP ceramics containing 10–12 mol% CeO_2 present much higher toughness ($15\text{--}20 \text{ MPa m}^{1/2}$) but lower strength (typically 600 MPa). This behavior is due to the larger grain size obtained in ceria-stabilized ceramics after sintering ($> 1.5\text{--}2.0 \mu\text{m}$), compared to that of 3Y-TZP ($< 300 \text{ nm}$). The Ce-TZP ceramics distinguish also from 3Y-TZP by a lower transformation critical stress (around 300 MPa), a higher t-m transformation temperature and a larger process zone (around $100\text{--}200 \mu\text{m}$ instead of a few μm in 3Y-TZP) (Shimozono *et al.*, 2006; Grathwohl and Liu, 1991). Because the tetragonal stabilization is not due to oxygen vacancies as for Y-TZP, Ce-TZP possesses higher stability in the presence of water.

Table 1 presents a comparison of the different zirconia ceramic properties.

Fig. 11 Diagram of a section through a free surface at (a) the sintering temperature. On cooling, particles of ZrO_2 near the surface (b) transform due to reduced constraint, developing a compressive stress in the matrix. The thickness of this compressively stressed layer can be increased (c) by abrasion or machining. Adapted from Stevens, R., 1986. *An Introduction to Zirconia*, second ed. London, England: Magnesium Elektron Ltd. (Magnesium Elektron Publication No 113).

It is important to note that this transformation toughening diminishes as the temperature increases because t-m transformation disappears above the phase transition temperature. Therefore, the PSZ and TZP are not high temperature materials. This strength reduction at higher temperatures can be compensated by adding other particles which will replace the transformation toughening by other mechanisms.

Compressive Surface Layers

Compressive surface layers are developed in zirconia based transformation toughened ceramics as a result of the spontaneous transformation of particles of tetragonal zirconia situated in or near the surface (Fig. 11). The easier transformation arises from the lack of hydrostatic constraint near the free surface, in the manner shown in Fig. 11.

A considerable increase in the fracture strength can be obtained by the generation of a large compressive surface stress. Furthermore, the magnitude of the surface stress can be increased considerably by any process such as grinding which generates stresses of a sufficient level internally to trigger the tetragonal - monoclinic transformation at greater than normal depths. The magnitude of the strengthening effect is dependent on the severity of grinding and transformation to the monoclinic phase can take place to depths of 100 μm . It is apparent that this phenomenon is only practical when the depth of the transformed layer is larger than the critical flaw size but small in comparison with the overall cross-section of the ceramic. The effect is of great significance in engineering components since for the first time a ceramic is available, which, when abraded or impacted as might happen to a component in manufacture or service, is stronger after the “damage” event than before it occurred.

Aging of Zirconia Ceramics (LTD)

The tetragonal to monoclinic transformation which is responsible for the toughening (when induced by stresses around propagating cracks in the volume) can also have a negative impact if it takes place spontaneously at the surface, a phenomenon known as Low Temperature Degradation. As a consequence, microcracking, grain pull-out and an increase of the surface roughness appear. In the worst case, it leads to premature failures, as was the case with the 3Y-TZP femoral head ruptures in 2001. This catastrophic episode of failures led to the prohibition of using Y-TZP ceramics in orthopedic applications (Chevalier *et al.*, 2009). Fig. 12 presents the model proposed by Yoshimura *et al.* (1987) to explain the stress increase which will trigger the t-m phase transformation, by water chemisorption and as-formed hydroxyl diffusion from the surface to the bulk. This diffusion would be favored by the presence of oxygen vacancies, especially numerous in Y-TZP ceramics. Fig. 13 illustrates the aging phenomenon showing the t-m nucleation in a surface grain, its propagation to the neighboring grains and the resulting microfissuration (Chevalier, 2006).

As the aging phenomenon is directly linked to oxygen vacancies created when stabilizing with cations of valence $< +4$ (e.g., with calcium, magnesium and yttrium addition), ceria-stabilized zirconia, owing to the tetravalent nature of cerium, possesses excellent aging resistance. Fig. 14 presents the results of accelerated aging kinetic assays performed in an autoclave at 134°C under 2 bars to simulate aging at 37°C for the 3-TZP and 10 Ce-TZP ceramics which confirms the excellent aging resistance of Ce doped zirconia (Chevalier *et al.*, 2009).

Synthesis of Doped Zirconia Powders for Ceramic Processing

The commercial grades of zirconia are produced by a number of routes, usually involving zircon as a precursor. Zircon is broken down into its constituents, ZrO_2 and SiO_2 , either chemically, by the addition of an aggressive alkali (NaOH , CaO), or by heating

to a high temperature, when the zircon dissociates into its constituent phases and separation occurs. The zirconia can then be removed by dissolution in sulfuric acid and is subsequently precipitated. The rate of reaction is governed by the particle sizes of the component phases and these are carefully controlled. Similarly, the morphology of the phases can have an influence on the process. Both these factors can be influenced by the processing temperature and the rate of cooling.

The zirconia can then be precipitated from solution when the variables employed control the nature of the precipitate, in particular, the size and morphology of the primary particles and the agglomerates. Calcination of the precipitate will then reduce the surface area of the powder and decrease its “reactivity”, but the primary structure of the particles and agglomerate will be retained. Thus, the powder manufacturing route will control the basic powder parameters of interest to the ceramist. Generally, the most active powders are produced by the sol-gel route, but due to their fine crystallite and particle size (they are often amorphous), these can be difficult to handle and shape prior to sintering. At the industrial level, micron-sized granules made of nanometric zirconia powders are employed. The powders which have gained greatest commercial acceptance are those which demonstrate sufficient surface area ($6\text{--}15\text{ m}^2\text{ g}^{-1}$) to enable sintering at relatively low temperatures but which have a macro-structure and shape which enables them to be easily handled (granule size $5\text{--}150\text{ }\mu\text{m}$).

Further improvement in the quality of powders is dependent on chemical homogeneity. In practice this is best achieved by the coprecipitation of the constituent oxides from a mixed solution. This is accomplished by titrating an acid solution of the soluble salts into a bath of aqueous ammonia. The mixed oxide is then washed several times and calcined in the temperature range $800\text{--}1000^\circ\text{C}$ to give a sinterable powder which is chemically homogeneous at an atomic level. To improve the handling characteristics, the powder is often granulated and it can be formed by a number of methods (e.g., spray drying).

Applications of Zirconia

Zirconia exhibits a number of desirable properties, notably high elastic modulus and hardness, a high melting point, a low friction coefficient and outstanding corrosion resistance. The microstructure can also be engineered such that very high fracture strength ($>1.5\text{ GPa}$) or high toughness ($>20\text{ MPa m}^{1/2}$) can be generated. Therefore, the material has found application in many markets particularly in wear, cutting, thermal barrier coatings, ionically conductive and biomedical applications (Palmero *et al.*, 2015). The traditional applications of zirconia have been in refractories for the glass industry, as color hosts in the pottery decoration industry, and as a component in many of the electronic ceramics available. In the following sections, two application fields of zirconia are outlined.

Refractories

The very high melting point and outstanding chemical resistance of zirconia make it a prime candidate for refractory applications where extreme conditions are experienced. It is a candidate material for components which are subject to high thermal shock, high

temperature and a corrosive environment such as a sliding gate valve in a continuous casting steel plant or in the nozzles and stoppers of transfer ladles. The superior performance of zirconia containing ceramics is believed to be due to the generation of a distribution of microcracks which can arrest the propagation of larger flaws generated as a consequence of thermal stresses. In this way the refractory although not having particularly high strength, has a superior crack stopping ability and is able to find applications in areas where the integrity of the structure is all important.

Stabilized zirconia has also been fabricated in the form of polycrystalline fibers for use as a thermal insulation blanket and this has a maximum temperature of $> 2100^{\circ}\text{C}$. In this temperature range the main heat transfer medium is radiative and the purpose of the fibers is to retain mechanical integrity, aided by the exceptional chemical stability of zirconia in conjunction with its high melting point.

A similar application in somewhat more arduous conditions occurs when thermal barriers are deposited on gas turbine engines using a plasma spray deposition process. Zirconia, as well as having the required thermal insulation properties, also has a thermal expansion coefficient close to that of the nickel based alloy substrate, thus minimizing breakdown due to stress generation arising from thermal cycling. An intermediate layer of nickel, chromium, aluminum, yttrium bond coat is often utilized to enhance the life of the coating. The most suitable composition is in the range 6–8 mol% Y_2O_3 and as would be expected with rapidly cooled material, the structure is non equilibrium, consisting of a mixture of cubic, non transformable tetragonal, and monoclinic phases. The whole structure is held together with a glassy bonding phase and interspersed with a network of fine randomly oriented microcracks. Use of this technology is now well established in stationary applications such as flame tubes and the technique is being further developed for rotating components.

Zirconia Electrolytes

The cubic phase has the fluorite structure in the stabilized systems based on $(\text{CaO}, \text{MgO}, \text{Y}_2\text{O}_3)\text{-ZrO}_2$ within specific compositional ranges. The void space generated by the presence of an oxygen ion vacancy is considered to be larger than for the corresponding Zr^{4+} vacancy and since the solute cations are of lower vacancy than zirconia, then there are many more of them. This accounts for the high ionic conductivity of the electrolyte to the oxygen species and its use as the membrane in oxygen sensors. These are commercially available for applications such as combustion control, atmosphere control, and monitoring oxygen content in metals.

A difference in oxygen partial pressure ($p = p_1 - p_2$) results in an electromotive force (EMF) being generated across the porous platinum electrodes according to the Nernst equation:

$$E = \frac{RT}{4F} \frac{p_2 \text{O}_2}{p_1 \text{O}_2} t \ln(p \text{O}_2) \quad (2)$$

For ionic conductivity $t = 1$ and the EMF generated is given by:

$$E = \frac{RT}{4F} \ln \frac{p_1 \text{O}_2}{p_2 \text{O}_2} \quad (3)$$

All measurements are based on the premise that thermodynamic equilibrium is present and that the kinetics of the electrode processes are sufficiently rapid that correct voltages are measured. The equation predicts that the EMF is dependent on temperature, which has been confirmed in many laboratories. On the basis of this, several important devices, such as oxygen sensors (Fig. 15) and monitors, oxygen pumps, and combined heat and electricity generating fuel cells are manufactured and are commercially available.

Fig. 15 Schema of a Lambda sensor. Adapted from Bosch.

Summary

Zirconia exhibits three crystallographic phases at atmospheric pressure: monoclinic, tetragonal and cubic. By alloying zirconia with oxides which are cubic at room temperature (i.e., MgO, CaO, Y₂O₃, CeO₂, etc.), it is possible to stabilize the zirconia cubic phase at room temperature. If the amount of cubic addition is too low, metastable tetragonal phase is obtained. The presence of these 2 phases governs the properties of the resulting material. Indeed, on the one hand cubic zirconia is an ionic conductor, being at the origin of electro-ceramics applications (sensor, actuator); on the other hand, the transformation under stress of metastable tetragonal zirconia into monoclinic phase is at the origin of the well known “transformation toughening” phenomenon leading to huge increase of mechanical properties, particularly fracture toughness, for bulk zirconia (PSZ, TZP) and for composites (e.g., ZTA).

Since the 1980s, new zirconia and zirconia based materials have been developed and applied to many more and various fields. The exceptional wear and corrosion resistance explain why seals in valves, chemical and slurry pumps are made of zirconia. As oxygen sensors, doped zirconia is used for fuel-air regulation in automobile engines. Zirconia particles are also used as reinforcing inclusions in ceramic matrices. The best known are alumina-zirconia composites which have superior strength, toughness and wear resistance when compared to conventional alumina and are used as cutting tools and in hip and knee prostheses. More recently, zirconia based nanocomposites have also been developed for biomedical applications (dental implants and other devices) combining several toughening mechanisms like t-m transformation, microcracking but also crack deviation due to the presence of elongated secondary phases (Palmero *et al.*, 2015; Chevalier *et al.*, 2020; Fornabairo *et al.*, 2017).

This is a reprint of M.J. Hoffmann, Si₃N₄-Ceramics, Structure and Properties of, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.02324-9.

Silicon nitride ceramics are composite materials, consisting of Si₃N₄ grains embedded in a matrix of amorphous or partially devitrified glass. They represent a whole class of materials with various properties depending on the volume fraction and composition of the grain-boundary phase as well as on the size and morphology of the Si₃N₄ grains. The microstructure is usually characterized by elongated grains surrounded by a fine-grained matrix. Since the elongated grains grow during the densification process, the resulting type of microstructure has been labeled as either self-reinforced or *in situ* toughened. Due to the self-reinforced microstructure, silicon nitride ceramics can exhibit an exceptionally high strength and toughness and make them interesting as structural components for numerous applications in engines and turbines. A steadily growing field of application is the use-as-wear parts in ball bearings and pumps, and they are widely used as cutting tools for the machining of cast iron (Chen *et al.*, 1993; Hoffmann and Petzow, 1994a). Relatively high thermal conductivities combined with a high strength for certain types of silicon nitride ceramics can also open new markets for electronic applications (Hirao *et al.*, 2001). More recently silicon nitride ceramics are discussed as potential materials for orthopedic applications, such as prosthetic hip and knee joints (Bal and Rahaman, 2012).

Crystal Structures

Silicon nitride has a density of 3180 kg m⁻³. During heating, it decomposes into liquid silicon and nitrogen gas at 1877 °C. The basic structural units are highly covalent bonded SiN₄ tetrahedra. They can be linked together in different ways to form three different modifications. The most stable phase is denoted as β-Si₃N₄ and crystallizes in the hexagonal space group P6₃. The α-Si₃N₄ also has hexagonal symmetry (P31c), but it is metastable and forms only at lower temperatures. A high-pressure modification with cubic symmetry has been discovered by Zerr *et al.* (1999). There is some evidence that α-Si₃N₄ is indeed a defect structure with a minor replacement of nitrogen atoms by oxygen atoms (Jack, 1976). The two forms cannot be transformed one to the other by a displacive transformation and a reconstructive process is necessary, usually in the presence of a liquid phase. The exact nature of the phase transformation is still not known. Both Si₃N₄ modifications can form solid solutions with Al₂O₃.

Processing and Microstructural Development

In general, silicon nitride ceramics are manufactured by standard powder metallurgical routes. The powder compacts are prepared by cold pressing, slip casting, or injection molding. Two basic types of silicon nitride ceramics are known: sintered silicon nitrides (SSN), and reaction-bonded silicon nitrides (RBSN). RBSN are prepared from silicon powder compacts, which are nitridated at 1100–1450 °C in a nitrogen atmosphere, usually under atmospheric pressure. The temperature–time program of the exothermic reaction depends on the geometry of the components and the particle size of the silicon powder. The final product shows a high porosity and, therefore a low strength, which limits the range of applications (Ziegler *et al.*, 1987). SSN are prepared from silicon nitride powder compacts. Due to the highly covalent bonding of the silicon nitride, densification can only be obtained by liquid-phase sintering using metal oxides such as MgO, Al₂O₃, Y₂O₃, or rare earth as sintering additives.

Most of the sintered silicon nitride ceramics are prepared by using α-rich Si₃N₄ powders which transform during sintering into β-Si₃N₄. The β-modification forms elongated grains if there is no pronounced grain impingement. The grain-growth anisotropy with the fast growth direction parallel to the crystallographic *c*-axis leads to a needle-like grain morphology with aspect ratios of up to 10, similar to whiskers. Grain anisotropy is strongly related to the additives used for densification. High-resolution and analytical transmission electron microscopy clearly indicates that growth sites for the attachment of silicon and nitrogen at the prism planes are blocked by rare earth ions (Shibata *et al.*, 2004; Winkelmann *et al.*, 2005). Thereby, the number of adsorbed rare earth atoms scales with the binding energy and is high for large atoms such as lanthanum (strong adsorption) and low for smaller atoms such as lutetium (minor adsorption) (Painter *et al.*, 2004). The adsorption of rare earth ions at the prism planes do not only influence growth anisotropy, but also has a strong impact on the mechanical properties.

A typical microstructure of an *in situ* toughened sintered silicon nitride ceramic is shown in Figure 1. By using pressure-assisted densification methods with pressures between 10 MPa (gas-pressure sintering) and 100 MPa (hot isostatic pressing), the sintering temperature could be raised above the decomposition temperature of silicon nitride and complete densification could be achieved even with small amounts of additives (2 vol.%) (Hoffmann *et al.*, 1999). Higher sintering temperatures also promote grain growth and an increase of the volume fraction of elongated grains. The second effect of an applied pressure is the reduction of the critical flaw size in the final product, which gives in an improvement in strength and reliability (Satet *et al.*, 2006).

Figure 1 Scanning electron micrograph of a plasma-etched silicon nitride microstructure. The dark particles are silicon nitride grains and the bright phase is the amorphous grain boundary.

An alternative manufacturing method for silicon nitride ceramics is based on a combination of the RBSN and SSN processes. The initial powder compacts consist of silicon powder and sintering additives. The silicon powder is first nitridated and subsequently postdensified at temperatures between 1750 and 1850 °C. The final product is denoted as SRBSN; it has a similar microstructure to the sintered silicon nitride ceramics (SSN) and comparable properties (Lee *et al.*, 2000).

One of the main features of a SSN microstructure is the formation of intergranular grain boundary films of a constant thickness at two-grain junctions between adjacent grains, as shown in Figure 2. The equilibrium film thickness is determined by the additive composition and varies between 1 and 2 nm. The intergranular films are always amorphous, whereas pockets at multigrain junctions could be crystallized (Kleebe *et al.*, 1992). High-temperature resistant silicon nitride materials mostly have crystallized multigrain junctions, while materials for applications in the temperature range below 1000 °C often reveal a completely amorphous grain-boundary phase.

The properties of the intergranular films that are controlled by the adsorption of rare earth elements at the prism planes, have a strong impact on the strength and toughness at room temperature, since *in situ* reinforcement not only requires high aspect ratio grains, but also a tailored interfacial strength to activate toughening mechanisms upon failure. There seems to be a contradiction between the development of high-strength or high-toughness materials and high-temperature resistant ceramics due to the fact that the intergranular film is on one hand responsible for the exceptional properties at lower temperatures, but on the other hand it limits the properties at temperatures above the softening point of the film. Indeed, high-temperature resistant silicon nitrides only reveal an intermediate strength and toughness level.

Mechanical Properties

Toughening in silicon nitride ceramics with a high volume fraction of elongated grains and a tailored interface between the glass matrix and the grains is attributed to crack-wake mechanisms. For structural applications, the fracture conditions will typically be governed by the presence of small flaws or defects present either in the as-sintered component or generated under in-service stresses. Because toughening mechanisms develop and become increasingly effective as a small crack extends and interacts further with the microstructure, the fracture resistance increases with crack size giving rise to so-called R-curve behavior. The rate of increase of the fracture resistance (steepness of the R-curve) with the initial extension of a small crack is quite important for catastrophic failure characteristics as the fracture-origin defects are typically below 30 μm in size for these type of materials (Becher, 1991; Kruzic *et al.*, 2008). More recent results revealed that the toughness of silicon nitrides increases from 2–3 MPa m^{1/2} to about 5–8 MPa m^{1/2} within the first 20 μm of crack extension. This steep increase is attributed to elastic bridges without debonding which requires an intermediate interfacial strength. Toughening mechanisms such as elastic bridging with debonding, frictional bridging or grain pull-out which rely on weaker interfaces do not significantly contribute to fracture resistance (Fünfschilling *et al.*, 2011).

Figure 2 High-resolution transmission electron micrograph of an intergranular grain boundary film of 1 nm thickness between two parallel silicon nitride grains (left side), with a transition to an amorphous multigrain junction on the right side.

Since fine-grained silicon nitrides exhibit a very steep R-curve with a maximum toughness up to $7\text{--}8 \text{ MPa m}^{1/2}$, a high strength up to 1400 MPa with a Weibull modulus between 20 and 30 could be obtained. However, there is significant strength degradation at temperatures above 1000 °C, when the intergranular films start to soften. Materials developed for high-temperature applications have a lower mean bending strength between 600 and 800 MPa, and crystallized multigrain junctions. The best high-temperature-resistant silicon nitrides can be used up to 1400 °C for several hundred hours without damage by oxidation or creep (Lofaj *et al.*, 2002). A further advantage of silicon nitride, in comparison to other structural ceramics, is the relatively high thermal shock resistance due to the low thermal expansion coefficient of $\sim 3 \times 10^{-6} \text{ K}^{-1}$. This means that high-strength silicon nitride ceramics can withstand temperature differences of more than 800 °C.

Conclusions

Silicon nitride ceramics have several excellent properties and clear advantages over other structural materials, but many potential applications are still not realized. A breakthrough in their use is inhibited not only by the high costs of the components for the automotive market, but also by the lack of knowledge of potential users which type of silicon nitride ceramic would fulfill best the demands during service: A silicon nitride developed as cutting tool to machine cast iron may not be the best materials solution as component in lubricated sliding systems or as component in gas turbines. However, the relatively complex interrelationships between the size and morphology of the Si₃N₄ grains, chemical composition and distribution of the grain-boundary phase offers a wide variety to tailor the microstructure and the resulting properties to meet the requirements of engineers for specific applications.

Si₃N₄ Ceramics, Structure and Properties

Monika Tatarková, Peter Tatarko, and Pavol Šajgalík, Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia

© 2021 Elsevier Inc. All rights reserved.

Silicon nitride (Si₃N₄) based ceramics are polycrystalline, composite materials, which consist of minimum two phases, i.e., silicon nitride grains and grain boundary phases. The individual silicon nitride grains are single crystals of one of the three possible crystallographic modifications of silicon nitride, α -, β -, or γ -Si₃N₄. On the other hand, the grain boundary phases are either amorphous or partially crystalline, and are formed during liquid phase sintering of starting silicon nitride powder. Therefore, the properties of the sintered Si₃N₄-based ceramics are not only pre-determined by the intrinsic properties of Si₃N₄ single crystals, but they strongly depend on the size, orientation and volume fraction of the Si₃N₄ grains, as well as the chemistry, and volume fraction of grain boundary phases. This all means that the properties of Si₃N₄ ceramics can be significantly improved by tailoring the microstructure.

Extensive research over the past five decades has significantly improved the mechanical and thermal properties of silicon nitride ceramics. Si₃N₄ ceramics with superior mechanical properties and high thermal conductivity may be obtained by the use of high-purity sub-micron powders, and careful selection of sintering aids. Due to its excellent combination of properties, such as low bulk density, low thermal expansion coefficient, good mechanical properties at high temperatures, high thermal shock resistance and resistance to chemical attack, and good tribological properties, Si₃N₄ can be used in a variety of structural applications, such as automotive engine parts, heat exchangers, pump seal parts, ball bearings, cutting tools and ceramic armors. In the last two decades, the use of silicon nitride has been broadened towards the electronic and biological, mainly orthopedic applications.

Single crystals of Si₃N₄

Structure

Si₃N₄ occurs in two crystalline phases at ambient pressure: α - and β -Si₃N₄. Both polymorphs have a hexagonal structure, but different stacking sequences: ABCD in α -Si₃N₄, while ABAB in β -Si₃N₄. Both modifications consist of SiN₄ tetrahedra, in which a Si atom lies at the center of a tetrahedron, and four N atoms at each corner. The SiN₄ tetrahedra are joined by sharing corners in such a way that each N is common to three tetrahedra. The idealized structure of β -Si₃N₄ has hexagonal symmetry with the space group either $P6_3$ (noncentrosymmetric) or $P6_3/m$ (centrosymmetric), while the idealized α -Si₃N₄ structure has trigonal symmetry of space group $P3_1C$ (Riley, 2000; Hardie and Jack, 1957).

The unit cell dimensions of the single crystals are listed in Table 1. A summary of the reported values from the individual works can be found in (Wang *et al.*, 1996). For β -Si₃N₄, the standard deviation is 0.005 Å and 0.004 Å for the *a*- and *c*-axis dimensions, while it is 0.014 Å and 0.008 Å for α -Si₃N₄. The greater deviation for α -Si₃N₄ is caused by a partial replacement of nitrogen in the N (1) site with oxygen (oxynitride), while the β -phase is a pure silicon nitride.

The α -phase is metastable (low temperature) modification of Si₃N₄, which always transforms into the β -phase (high temperature modification) at high temperatures. This transformation requires a lattice reconstruction that cannot occur by a displacive transformation, but can occur via solution-precipitation process above 1400°C or by vapor phase process above 1600°C (Zhu and Sakka, 2008). The reverse β to α transformation has never been observed (Riley, 2000). Therefore, β -Si₃N₄ is the major form used in Si₃N₄ ceramics.

A third polymorph of Si₃N₄, cubic phase with spinel structure (γ -Si₃N₄) was discovered in 1999 by synthesis at pressures above 15 GPa and temperatures exceeding 1700°C (Zerr *et al.*, 1999). The cubic Si₃N₄ spinel phase of space group $Fd-3m$ ($z = 8$) contains two different constituting units, i.e., SiN₄ tetrahedra and SiN₆ octahedra in a 1:2 ratio. Thus, the cubic phase may be better described as Si[Si₂N₄] instead of Si₃N₄.

Properties

A summary of the properties of single crystals of silicon nitride is given in Table 2. Similar to the unit-cell dimensions, the density of silicon nitride also slightly varies, depending on the real structure of Si₃N₄, but the list of all available data can be found in (Wang *et al.*, 1996). The density of γ -Si₃N₄ exceeds that of hexagonal structures by around 20%, due to a significantly closer atomic packing in the crystal structure.

The longer stacking sequence in α -Si₃N₄ results in its higher hardness when compared to β -Si₃N₄, however, the hardness of the cubic γ -Si₃N₄ is significantly higher than that of hexagonal phases. The hardness of both α -Si₃N₄ and β -Si₃N₄ is significantly anisotropic (Chakraborty and Mukerji, 1982). Recently, the effect of crystal orientation on nanohardness and indentation modulus of silicon nitride was studied by nanoindentation. The {10 $\bar{1}$ 0 [0001]} slip system was found to have the most significant effect on hardness anisotropy of β -Si₃N₄ (Csanádi *et al.*, 2016).

Table 1 Unit-cell dimensions of three modifications of silicon nitride, α -, β -, and γ -Si₃N₄

Crystallographic modification of Si ₃ N ₄	<i>a</i> -lattice parameter (Å)	<i>c</i> -lattice parameter (Å)
α -Si ₃ N ₄	7.818(3) (Kato <i>et al.</i> , 1975)	5.591(4) (Kato <i>et al.</i> , 1975)
β -Si ₃ N ₄	7.595(1) (Grun, 1979)	2.9023(6) (Grun, 1979)
γ -Si ₃ N ₄	7.7381(2) (Zerr <i>et al.</i> , 1999)	–

Table 2 Properties of all three known crystal modifications of Si₃N₄, α -, β - and γ -phase

Property	α -Si ₃ N ₄	β -Si ₃ N ₄	γ -Si ₃ N ₄
Density (calculated) [g cm ⁻³]	3.150–3.178 (Wang <i>et al.</i> , 1996)	3.213–3.214 (Wang <i>et al.</i> , 1996)	3.93 (Zerr <i>et al.</i> , 1999)
Hardness; prismatic plane (direction $\parallel$ to the <i>c</i> -axis) [GPa]	51.76 (HV0.1)–33.06 (HV0.5) (Chakraborty and Mukerji 1982)	36.96 (HV0.1)–21.36 (HV0.5) (Chakraborty and Mukerji 1982)	30–43 (HV0.5) (Zerr <i>et al.</i> , 2002)
Hardness; basal plane (direction $\perp$ to the <i>c</i> -axis) [GPa]	38.59 (HV0.1)–25.55 (HV0.5) (Chakraborty and Mukerji 1982)	20.43 (HV0.1)–14.45 (HV0.5) (Chakraborty and Mukerji 1982)	
Tensile strength (calculated)	up to $\sim$ 51 (Ogata <i>et al.</i> , 2004)	up to $\sim$ 57 (Ogata <i>et al.</i> , 2004)	$\sim$ 45 (Kocer <i>et al.</i> , 2003)
Bulk modulus (calculated) [GPa]	257–263 (Ogata <i>et al.</i> , 2004)	225–292 (Ogata <i>et al.</i> , 2004)	290 (Zerr <i>et al.</i> , 2002)
Shear modulus (calculated) [GPa]	132 (Ogata <i>et al.</i> , 2004)	112–116 (Ogata <i>et al.</i> , 2004)	258–261 (Zerr <i>et al.</i> , 2002)
Thermal conductivity (calculated) (direction $\parallel$ to the <i>c</i> -axis) [W m ⁻¹ K ⁻¹]	170 (Hirosaki <i>et al.</i> , 2002)	225 (Hirosaki <i>et al.</i> , 2002)	80 (Morelli and Heremans 2002)
Thermal conductivity (calculated) (direction $\perp$ to the <i>c</i> -axis) [K ⁻¹]	105 (Hirosaki <i>et al.</i> , 2002)	450 (Hirosaki <i>et al.</i> , 2002)	
Coefficient of thermal expansion (direction $\parallel$ to the <i>c</i> -axis) [K ⁻¹]	3.61×10^{-6} (Henderson and Taylor 1975)	3.72×10^{-6} (Henderson and Taylor 1975)	3.89×10^{-6} (Jiang <i>et al.</i> , 2002)
Coefficient of thermal expansion (direction $\perp$ to the <i>c</i> -axis) [K ⁻¹]	3.70×10^{-6} (Henderson and Taylor 1975)	3.23×10^{-6} (Henderson and Taylor 1975)	

Contrary to the hardness, fracture toughness is relatively isotropic, but both significantly decrease with increasing temperature (Reimanis *et al.*, 1996). The ab initio calculations also showed that the tensile strength of an β -Si₃N₄ crystal is the highest among all of three modifications of Si₃N₄ (Ogata *et al.*, 2004).

The coefficient of thermal expansion as well as the thermal conductivity of both α - and β -phases are also anisotropic, but the anisotropy is more significant in the case of β -phase. The coefficient of thermal expansion of the γ -phase is the highest among of all three configurations. On the other hand, the intrinsic thermal conductivity of β -Si₃N₄ is clearly the highest, while the other two structures have thermal conductivity at a very similar level.

Preparation

Two major crystal structure of Si₃N₄, hexagonal α - and β -phases, attracted main attention of the researchers to develop and investigate single crystals. The single crystals were produced either by the CVD process (mainly α -Si₃N₄) (Kijima *et al.*, 1974) or by the growth from Si melts (mainly β -Si₃N₄) (Inomata and Yamane, 1974). When the silicon melt contains a small amount of Fe ($\sim$ 1 wt%), α -Si₃N₄ single crystals could be grown along with β -Si₃N₄ single crystals (Chakraborty and Mukerji, 1980). However, the size of the single crystals was usually limited to the dimensions of several hundred μ m up to several mm (Reimanis *et al.*, 1996).

With the beginning of the era of one dimensional nanostructured materials, the research on the preparation of Si₃N₄ single crystals shifted towards the development of Si₃N₄ single crystal nanobelts (Yang *et al.*, 2005a), nanowires (Yang *et al.*, 2005b) or whiskers (Yang *et al.*, 2004). The materials are usually only a few nm thick, but their length can be from several hundred μ m up to several tens of mm. A variety of synthesis techniques have been used to produce these materials, including chemical vapor deposition, direct nitridation, carbothermal reduction, and laser and plasma synthesis. Such 1D materials are promising candidates for matrix enhancement of composites in aerospace applications, metallurgy industry, and aviation and military hardware. They are also wide-band gap semiconductors and can be introduced to nano-devices to tailor electronic and optical properties (Yang *et al.*, 2004). This is currently the most promising utilization of silicon nitride single crystals, as the manufacturing of large-scale single crystals is very difficult. On the other hand, the excellent properties of Si₃N₄ single crystals are exploited in its polycrystalline form (sintered Si₃N₄), in which the individual grains of Si₃N₄ (α - or β -phase single crystals) are embedded in a matrix of amorphous or partially crystalline phase.

Polycrystalline Si₃N₄

Silicon nitride is mostly produced from α -Si₃N₄ powder, which is transformed to β solid solution during liquid phase sintering via the solution-precipitation process. Due to the low self-diffusion coefficient of Si₃N₄ and the highly covalent Si–N bonds, densification requires the use of sintering additives. The additives form a liquid phase during sintering at high temperatures by their reactions with SiO₂ or oxynitrides, which are always present on the surface of Si₃N₄ powders. The presence of a liquid phase significantly facilitates the densification of silicon nitride. Upon cooling, the liquid solidifies to form amorphous or partially crystallized oxynitride glassy phases at the grain boundaries of Si₃N₄ grains (single crystals) (Hampshire and Pomeroy, 2012).

Preparation of silicon nitride has mainly been conducted using so-called conventional sintering techniques, such as hot pressing (HP), gas pressure sintering (GPS), hot isostatic pressing (HIP), and pressureless sintering (PS). More recently, unconventional sintering techniques, such as spark plasma sintering (SPS) and microwave sintering (MS) have attracted attention due to their advantages over conventional sintering techniques, such as reduced sintering time and temperature, possibility to produce a unique microstructure that would not be possible to achieve using conventional routes. The SPS technique can enhance the sinterability of Si₃N₄ with controlled grain growth and phase transformation at reduced temperatures (Nishimura *et al.*, 1995; Belmonte *et al.*, 2010). The activation energy for phase transformation using the SPS process is much higher than for the conventional process, such as HP (Suganuma *et al.*, 2003). A homogenous Si₃N₄ nanomaterial with an average grain size as low as 70 nm can be prepared by SPS (Xu *et al.*, 2005). Similarly, the significantly enhanced densification and phase transformation were observed when microwave heating was applied during processing of Si₃N₄ (Zhang *et al.*, 1992). The α - β transformation occurs at lower temperature ($\sim 1500^\circ\text{C}$) than in the case of conventional techniques ($\sim 1750^\circ\text{C}$), due to lower viscosity of grain-boundary glassy phase caused by selective localized heating of microwaves (Chockalingam and Earl, 2010).

Regardless of the sintering technique used, densification of sintered Si₃N₄ always consists of the same steps, including formation of liquid phase, solution-precipitation process, grain growth, solidification and partial crystallization of the grain boundary phase. Therefore, common characteristics of microstructure development of Si₃N₄ and their relations to the final properties will be discussed in the next sections.

Development of Si₃N₄ Microstructure

The evolution of microstructure of Si₃N₄ is mainly controlled by the starting Si₃N₄ powder, type and amount of sintering additives, and sintering parameters. This all significantly affects the α - β transformation during sintering, and the final microstructure of Si₃N₄. The β -phase grows on the nuclei, which are the result of heterogeneous nucleation, as homogenous nucleation does not play an important role (Šajgalík and Galusek, 1993).

The starting powder usually contains different amounts of α and β phases, but mainly α -rich powders are used. The number of β -Si₃N₄ (pre-existing β -grains) determines the number of elongated β -Si₃N₄ in the final microstructure. A small amount results in a large interparticle distance between β -grains, thus the grains are able to grow during sintering without significant impingement by other grains (Šajgalík and Galusek, 1993). During sintering, the metastable α -phase and the subcritical β -phase ($< 0.5\ \mu\text{m}$) dissolve in the liquid due to their higher chemical potential, and then re-precipitate on the larger pre-existing β -grains (Petzow and Herrmann, 2002). The largest β -grains dominate the grain growth process and establish the fraction of large, elongated grains in the final microstructure (Becher *et al.*, 1998).

On the other hand, if the starting mixture contains a large amount of β -phase ($> 30\ \text{vol}\%$), the driving force for the solution-precipitation process is much smaller (Petzow and Herrmann, 2002). In this case, the final microstructure will consist of fine, equiaxed grains. Similarly, the equiaxed β -Si₃N₄ microstructure can be produced when the starting powder consists only of β -phase (Becher, 1991).

Fig. 1 shows an example of two microstructures of Si₃N₄, which were obtained after SPS sintering of the same starting powder mixture of Si₃N₄:Y₂O₃:Al₂O₃ (93:5:2 wt%) at different temperatures (1600°C versus 1750°C). The amount of α -Si₃N₄ in the initial

Fig. 1 Typical equiaxed microstructure of silicon nitride with a high content (82%) of the α -phase (a), and fully transformed microstructure (100% β -phase) consisting of the elongated grains (b).

Si₃N₄ powder was > 95%. The sintering at a lower temperature resulted in a microstructure with more equiaxed grains (Fig. 1(a)), while the increase in the temperature led to a significant increase of the number of large elongated β -Si₃N₄ grains (Fig. 1(b)). Indeed, the Rietveld analysis of the XRD data confirmed that only a small amount of the β -phase was present in the first case (18% β -Si₃N₄), while the complete transformation (100% β -Si₃N₄) occurred during sintering at 1750°C.

It is generally accepted that prismatic planes of the hexagonal grains of Si₃N₄ are more stable when compared to basal planes. The hexagonal crystals grow preferentially along the c-axis direction to form elongated, needle-like grain morphology. This is related to the Si₃N₄ crystal structure, in which it is energetically more favorable for a surface nucleus to attach to a basal plane than to a prismatic plane. The growth mechanism is diffusion controlled for the basal plane, while the growth rate is determined by the formation of surface nuclei on the prismatic planes. Therefore, the growth rate of the basal plane is much faster (along the c-axis) than that of prismatic planes (Petzow and Herrmann, 2002; Satet *et al.*, 2006). One of the main factors of elongated grain formation is the viscosity of the liquid phase formed during sintering (Becher *et al.*, 2008). The liquid with higher viscosity hinders both the heterogeneous nucleation and material transport, which promotes the preferential growth of the pre-existing β -grains and formation of β -Si₃N₄ grains with a higher aspect ratio (Bressiani *et al.*, 1999).

Grain boundary phases of Si₃N₄

Upon cooling from sintering temperature, a liquid solidifies in the form of an amorphous or a partially crystalline phase at the grain boundaries of Si₃N₄. Therefore, the type and amount of sintering additives not only improve densification, but also pre-determine the chemistry and quantity of the resulting grain boundary (GB) phases.

Very often, post-sintering heat treatment is necessary for devitrification of the GB phase, as an amorphous phase is not in an equilibrium condition according to the phase diagram. However, HRTEM analysis revealed that the devitrification of the glassy phase is not completed even after heat treatment (Liu and Nemat-Nasser, 1998). A residual glass remains at the tip of each triple junction, along with the amorphous film between two Si₃N₄ grains, or between Si₃N₄ and a crystalline secondary phase. The thickness of the amorphous phase (~ 0.5–3 nm) depends on the temperature, additive composition and impurities of the starting powder (Petzow and Herrmann, 2002), but does not depend on the amount of the sintering additives used (Hampshire and Pomeroy, 2012). The description of the manner of crystallization of the GB phases is described in (Liu and Nemat-Nasser, 1998).

Effect of rare-earth oxides on the microstructure development of Si₃N₄

The type of sintering additives strongly affects the viscosity of a liquid phase by altering the glass composition, which determines the diffusion rates of silicon and nitrogen, and thereby the grain growth rate. Initially, silicon nitride was sintered using additives, such as MgO, Al₂O₃, Y₂O₃ or their mixtures. Later, rare earth (RE) oxides (RE₂O₃) attracted attention, mainly due to their refractory nature (enhancing the high temperature properties), but also due to their significant effect on the microstructure development, which can be tailored by the use of different RE-based oxides. The effect of RE oxides on the microstructural development of Si₃N₄ is related to the different viscosities of RE-containing glassy phases at sintering temperatures, which significantly increase with a decreasing ionic radius of RE³⁺ (i.e., from La to Lu) (Becher and Ferber, 2004; Hampshire and Pomeroy, 2004).

The RE₂O₃ additives control the rates of $\alpha \rightarrow \beta$ phase transformation, the grain growth anisotropy, and the aspect ratio of β -Si₃N₄ grains (Satet and Hoffman, 2005). The activation energy for $\alpha \rightarrow \beta$ transformation is higher when a larger ionic radius RE is considered, which results in the slower phase transformation at the same annealing temperature when compared to the RE with a smaller ionic radius (Kitayama *et al.*, 2006). In addition, the temperatures of initiation and completion of the phase transformation decrease with a decreasing ionic radius of RE (Becher *et al.*, 2010).

The role of RE₂O₃ additives during liquid phase sintering of Si₃N₄ is changed when some other oxides are added to the composition. The effect of La₂O₃ versus Lu₂O₃ in a system with low viscosity (in combination with MgO, or Al₂O₃) is opposite of that observed for a high viscosity system (in combination with SiO₂). The detailed explanation can be found in Becher *et al.* (2010). This was clearly experimentally confirmed as for the Si₃N₄ system with the RE₂O₃ and MgO additives (low viscosity system) the aspect ratio of β -Si₃N₄ grains increased with increasing RE³⁺ in the RE₂O₃ additives (Satet and Hoffman, 2005). On the other hand, the aspect ratio of β -Si₃N₄ grains increased with decreasing RE³⁺ for the Si₃N₄ composition with the RE₂O₃ and SiO₂ as the only additives (Lojanová *et al.*, 2010; Tatarko *et al.*, 2010).

Self-reinforced microstructure of Si₃N₄

Self-reinforced β -Si₃N₄ microstructure is an analog to a whisker-reinforced microstructure, in which the elongated rod-like grains (which are similar to whiskers) toughen the materials (Becher *et al.*, 1998). Such reinforcement is possible due to the fact that the growth rate of β -grains along the c-axis significantly exceeds the growth rate of the grains in the direction perpendicular to the c-axis direction.

The formation of elongated β -Si₃N₄ grains with a high aspect ratio can be controlled by the addition of appropriate sintering additives as they would alter the viscosity of the liquid during sintering, thereby modifying the diffusion rates of Si and N. The size and the number of elongated grains in the final microstructure can also be affected by the α/β ratio of the starting powder (the fraction of β -Si₃N₄ in the powder) (Becher *et al.*, 1998; Šajgalík *et al.*, 1995). A broad size distribution leads to abnormal grain growth. On the contrary, when a narrow particle size distribution of β -grains is used, a material with rather homogenous microstructure will be formed. The use of a rather higher temperature (in the range of 1800–2000°C) will help to develop a self-reinforced microstructure, due to the fact that a mass transport at the grain boundaries will be enhanced. The effect of the presence of the β -phase in the starting powder can even be enhanced by the use of elongated β -seeds in the starting powder. The larger the

seeding particles, a significant distinct bimodal size distribution microstructure can be obtained (Becher *et al.*, 1998). This type of elongated β -morphology is typical of dense Si₃N₄ prepared from α -Si₃N₄ rich starting powders and is very important for the improvement of mechanical properties.

Textured microstructure of Si₃N₄

Superior properties of silicon nitride can be achieved by the formation of a textured microstructure, in which the elongated β -Si₃N₄ grains are oriented. The textured Si₃N₄ can be manufactured by various techniques, such as hot pressing, hot forging, sinter forging, templated grain growth, and strong magnetic field alignment. Details, including theoretical models and review of the research works, can be found in Zhu and Sakka (2008). In the case of high temperature processes (hot pressing, hot forging, or sinter forging), a textured microstructure is formed due to the rotation of elongated β -Si₃N₄ grains induced by a uniaxial stress applied during sintering or forging, followed by their preferential growth along the c-axis direction. On the other hand, the templated grain growth technique relies on the abnormal epitaxial growth of β -Si₃N₄ grains on the initially oriented β -Si₃N₄ seeds (or template) by the consumption of the fine-grained matrix during sintering.

Highly textured silicon nitride can be prepared by slip casting (Zhu and Sakka, 2008) or gel casting (Yang *et al.*, 2014) in a strong magnetic field of $> 6T$. When a strong magnetic field is applied, the Si₃N₄ crystals will become oriented during the slurry forming process. This technique relies on the fact that when diamagnetic or paramagnetic particles with anisotropic magnetic susceptibility are suspended in a liquid medium and placed in a magnetic field, they will rotate to an angle to minimize the system energy. Due to the higher magnetic susceptibility of silicon nitride crystals in the a-, b- directions than that of the c-axis direction ($\chi_{a,b} > \chi_c$), the Si₃N₄ crystals will be aligned with their a-, b-axes parallel to the magnetic field. In order to align the c-axis of Si₃N₄, rotating magnetic field must be used during slip casting. The β -Si₃N₄ crystals exhibit stronger texturing ability than the α -Si₃N₄ due to their higher anisotropic magnetic susceptibility when compared to the α -phase (Zhu and Sakka, 2008). The use of β -Si₃N₄ in the starting powder may enhance the degree of orientation and form a microstructure with more significant bimodal grain size distribution.

Properties of Polycrystalline Si₃N₄

Room temperature mechanical properties

Room temperature mechanical properties of Si₃N₄ mainly depend on the microstructure of the material (α/β ratio, grain size, amount and chemistry of GB phases), which can be controlled by the amount and/or type of sintering additives, as well as by the densification and sintering conditions used. As an example, Table 3 demonstrates how significantly the mechanical properties of Si₃N₄ can vary when the same starting mixture is sintered at two different temperatures, resulting in a different α/β ratio in the final microstructures. The starting mixture of Si₃N₄:Y₂O₃:Al₂O₃ = 93:5:2 wt% was sintered by SPS at different temperatures (1600°C and 1750°C), while using the same mechanical pressure of 50 MPa and the dwell time of 7 min. In both cases, the GB phases were amorphous, so the effect of different chemistry of the GB phase can be neglected. On the other hand, the α/β ratio significantly changed, as the sintering at 1600°C led to a limited α/β transformation (only 18% of β -Si₃N₄), while the α -phase fully transformed into the β -phase when sintered at 1750°C (100% of β -Si₃N₄). The representative microstructures of both materials are shown in Fig. 1. In agreement with the α -phase having the higher hardness, the hardness of the Si₃N₄ with majority of α -grains is higher by ~ 3 GPa than that of Si₃N₄ with 100% β -Si₃N₄ grains. On the other hand, the positive effect of the presence of elongated β -Si₃N₄ is clearly observed for the strength and fracture toughness of Si₃N₄ (Table 3).

Hardness

Hardness of silicon nitride mainly depends on the phase transformation of Si₃N₄ because of the significant difference between the hardness of α - and β -phases (see Section “Properties”). Generally, the material with a higher amount of α -Si₃N₄ exhibits a higher hardness when compared to the material with majority of β -Si₃N₄. Hardness of β -Si₃N₄ increases with a decreasing amount of grain boundary phase as well as with a decreasing grain diameter. Usually, the hardness of β -Si₃N₄ is at the level of ~ 12 GPa for a material with coarse grained microstructure and/or a high additive content, while it reaches a value of ~ 20 GPa for the material with a fine grained microstructure and/or low additive content (Petzow and Herrmann, 2002).

Table 3 Mechanical properties of the same material composition (Si₃N₄:Y₂O₃:Al₂O₃) sintered at different temperatures (1600°C and 1750°C) by SPS, resulting in a different α/β ratio

The amount of β -Si ₃ N ₄ phase	18% β -Si ₃ N ₄ grains	100% β -Si ₃ N ₄ grains
Grain size [nm]	165 $\pm$ 77	235 $\pm$ 131
Aspect ratio of grains	1.7 $\pm$ 0.6	2.0 $\pm$ 0.9
Young's modulus [GPa]	317 $\pm$ 1	290 $\pm$ 1
HV5 [GPa]	18.1 $\pm$ 0.7	15.0 $\pm$ 0.3
Flexural strength [MPa]	424 $\pm$ 97	736 $\pm$ 36
Fracture toughness (Chevron notch) [MPa m ^{1/2}]	3.1 $\pm$ 0.1	5.5 $\pm$ 0.3

The hardness of Si₃N₄ can also be affected by the chemistry of GB phases. It was shown that the hardness of Si₃N₄ (HV1) increases with a decreasing cation radius of RE³⁺ in RE₂O₃ (e.g., when La is replaced with Lu) from ~ 17 GPa to ~ 15.4 GPa (Lojanová *et al.*, 2010). This is due to the fact that the presence of a RE element with the smaller cation size increases cationic field strength of the glassy phase, which in turn increases the hardness of the whole Si₃N₄ body.

Strength

Flexural strength of fully dense Si₃N₄ varies in the range of 800–1400 MPa, depending on the presence of processing defects, such as pores, inclusions, agglomerates, etc. (Petzow and Herrmann, 2002). Si₃N₄ with a fine, submicrometer grained microstructure reaches the highest fracture strength of more than 1000 MPa. Generally, the strength decreases as the grain size increases. However, the increase of the strength with increasing grain size was observed for the self-reinforced microstructure, in which the flexural strength can be as high as ~ 1100 MPa (Becher *et al.*, 1998). When the large, elongated grains do not come into contact with each other and are dispersed uniformly in the fine equiaxial grained matrix, the strength of Si₃N₄ is not reduced. The large grains or a cluster of large grains act as fracture flaws, which significantly deteriorate the strength of Si₃N₄ (Hirotsaki *et al.*, 1993).

By developing the textured Si₃N₄, the strength can be maximized in one direction, usually in the direction perpendicular to the grain alignment (to the c-axis of Si₃N₄). The superior strength of Si₃N₄ was observed when the textured microstructure was prepared using seeding and tape casting (1100 MPa) (Hirao *et al.*, 1995), seeding and extrusion techniques (1400 MPa) (Teshima *et al.*, 1999), or sinter-forging method (2100 MPa) (Kondo *et al.*, 1999).

The strength of sintered Si₃N₄ also depends on the chemistry of GB phases. The bending strength of Si₃N₄ increases with a decreasing ionic radius of RE³⁺ in the GB phase. This was observed for both the fully amorphous RE-based GB phase (from ~ 880 MPa for La-containing GB phase to 1050 MPa for Lu-containing GB phase) (Satet and Hoffman, 2005) and crystalline RE₂Si₂O₇ type of GB phases (from ~ 520 MPa for La-based GB phase to ~ 700 MPa for Lu-based GB phase) (Tatarko *et al.*, 2010). The decrease in the strength caused by the use of a RE with larger RE³⁺ can be explained by the decrease in grain-GB interfacial strength with an increasing size of RE³⁺. Weak interfaces could induce a growth of natural flaws to a critical size at lower loads, resulting in a lower bulk strength (Satet and Hoffman, 2005).

Fracture toughness

A relatively low fracture toughness of sintered Si₃N₄ was initially a major barrier to the wide structural application of Si₃N₄. Therefore, the improvement of fracture toughness and the development of self-reinforced microstructures have been the two most investigated areas in the silicon nitride research field. Typical monolithic silicon nitride ceramics fabricated using α-Si₃N₄ raw powder exhibits fracture toughness in the range of 3–6 MPa m^{1/2}. The fracture toughness can be increased to 8–14 MPa m^{1/2} for self-reinforced Si₃N₄.

Fracture toughness of Si₃N₄ depends mainly on the shape and size of grains and the composition of the grain boundary phases. The dominant toughening mechanisms are controlled by the diameter and volume fraction of the large elongated grains (Tatarko *et al.*, 2010; Šajgalík *et al.*, 1995). Pull-out and elastic bridging were most frequently observed in the fine-grained microstructure with tailored, needle-like β-Si₃N₄ grains with diameters of < 1 μm. On the other hand, crack deflection was the main toughening mechanism observed in Si₃N₄ with coarse-grained microstructures having grains with diameters of > 1 μm. Silicon nitride with a microstructure having the highest volume fraction of grains with aspect ratio > 4 shows the highest fracture toughness of > 8 MPa m^{1/2} (Šajgalík *et al.*, 1995).

The presence of large elongated β-Si₃N₄ grains in the microstructure is essential for the improvement of fracture toughness, but still does not guarantee the occurrence of the toughening mechanisms. One of the critical issues in microstructural design of Si₃N₄ is to control the debonding at the interface between the β-Si₃N₄ and the intergranular glassy phase to enable crack deflection and crack bridging (Becher *et al.*, 1998). The interfacial debonding strongly depends on the chemistry of GB phases, which is directly determined by the composition of the sintering additives used. It was clearly demonstrated that the fracture toughness of silicon nitride increases with increasing Y/Al and O/N ratios in the additives, due to the enhanced interfacial debonding (Sun *et al.*, 1998). Similarly, RE elements also affect the interfacial bonding strength of silicon nitride. Their role is different when some other additives are simultaneously used, as described in the case of microstructure development (Section “Effect of Rare-Earth Oxides on the Microstructure Development of Si₃N₄”). For the low viscosity system (RE₂O₃ + MgO or Al₂O₃) and/or amorphous GB phases, the fracture toughness of silicon nitride increases with an increasing size of RE³⁺ (when Lu is replaced with La) from 5.5 MPa m^{1/2} to 7.2 MPa m^{1/2} (Satet and Hoffman, 2005). On the other hand, for the high viscosity system (RE₂O₃ + SiO₂) and crystalline GB phases, the fracture toughness of silicon nitride shows the opposite behavior, as it increases with a decreasing size of RE³⁺ (when La is replaced with Lu) from ~ 4.7 MPa m^{1/2} to ~ 7 MPa m^{1/2} (Tatarko *et al.*, 2010).

As with the strength of silicon nitride, the fracture toughness can also be significantly improved by the texturing of the microstructure, which exceeds the level of 10 MPa m^{1/2} and can reach up to ~ 14 MPa m^{1/2} for the textured Si₃N₄ developed using seeding and tape casting or seeding and extrusion techniques, respectively (Hirao *et al.*, 1995; Teshima *et al.*, 1999).

High temperature mechanical properties

At temperatures above 1000°C, the softening of the GB phases occurs, which significantly affects the high temperature properties of silicon nitride. Therefore, GB chemistry, effective viscosity and volume fraction of the GB phases will control the high temperature behavior of Si₃N₄, such as oxidation and creep resistance.

Fig. 2 Back-scattered SEM images of cross sections of Si₃N₄ with La₂O₃ (a) or with Lu₂O₃ (b) after the oxidation test at 1400°C for ~ 200 h.

Oxidation resistance

When pure silicon nitride is exposed at high temperatures (above 1000°C) in oxidizing atmosphere, a layer of pure silica (SiO₂) is formed on its surface. The diffusion of oxygen through the SiO₂ layer is the rate-controlling step, leading to a parabolic oxidation kinetic (Klemm, 2010). When Si₃N₄ contains sintering additives, some additional crystalline and/or amorphous silicates are formed in the SiO₂ layer. These phases weaken the pure SiO₂ layer, which results in the higher oxygen diffusion through the layer into the ceramic body when compared to the materials without additives (Klemm, 2010). In the case of Si₃N₄ with additives, both the inward diffusion of oxygen and the outward diffusion of cations of additives and nitrogen result in the formation of a compositional gradient in the material beneath the oxide layer (Cinibulk *et al.*, 1992). To relax this chemical gradient, the diffusion of cations of additives to the surface occurs, which is followed up by the evolution of a higher amount of gaseous reaction products, causing the formation of bubbles on the surface layer (Klemm, 2010).

In order to improve the oxidation resistance of multiphase silicon nitride, the following requirements are necessary (Andrews and Riley, 1989):

- (1) Minimum quantity of intergranular phases.
- (2) Presence of additives with low mobility of their cations.
- (3) Presence of crystalline GB phases.
- (4) During oxidation, a high eutectic temperature composition in the system: oxidation product/SiO₂ must be formed.

The oxidation resistance of Si₃N₄ can be associated well with the refractoriness of the GB phases, i.e., it is inversely related to the eutectic temperature in the system. The refractory nature of GB phases mainly determines the diffusion rate of cations and anions along the residual amorphous GB phase. Due to the greater cation field strength, the more refractory GB phases are expected for Si₃N₄ sintered with RE oxides having a smaller cation size of RE³⁺ (Cinibulk *et al.*, 1992; Tatarko *et al.*, 2013). Fig. 2 shows back-scattered SEM images of cross sections of the oxidation layer for Si₃N₄ with La₂O₃ (Fig. 2(a)) and Si₃N₄ with Lu₂O₃ (Fig. 2(b)). A significantly greater amount of La³⁺ diffused into the surface layer when compared to the Lu³⁺ cations. This confirms that the highly refractory Lu₂O₃-SiO₂ composition significantly hinders the diffusion of cations towards the surface layer, thereby improving the oxidation resistance of Si₃N₄. On the other hand, the greater mobility of additive cations leads to the formation of a zone depleted by RE cations, in which the grain boundaries between the Si₃N₄ grains are completely free of the former GB phase (La³⁺ cations).

Creep resistance

Creep deformation mostly takes place at the grain boundaries, therefore, the viscosity and refractory nature of GB phases again play an important role in improving the creep resistance of Si₃N₄.

The creep deformation in Si₃N₄ can occur either via so called “cavitation” or “non-cavitation” (viscous flow or solution-precipitation process) creep. In most of the sintered Si₃N₄ materials, particularly in high-viscosity systems, cavity formation is not observed after creep deformation. This suggests that only volume-conservative mechanisms, such as viscous flow, grain boundary sliding and solution-precipitation processes are occurring. The grain boundary sliding is an integral part of the viscous flow. The viscous flow can occur due to the decreased viscosity of the GB phase at high temperatures. Under the effect of an external stress at high temperatures, the grains approach each other (grain boundary sliding), so the GB phase is squeezed out or flows away from the area between the grains. Viscous flow creep cannot be the main controlling mechanism, but it is rather considered as a transient process responsible for the primary creep regime, up to about 1% strain (Meléndez-Martínez and Domínguez-Rodríguez, 2004). Apparently, the only possible mechanism to rationalize the deformation process of silicon nitride with highly refractory GB phase is the solution-precipitation process (Lofaj and Wiederhorn, 2009).

Since in most silicon nitride systems the glass melts at lower temperatures than those at which diffusion becomes significant, the Si₃N₄ crystals dissolve in the liquid phase at the grain boundaries subjected to compression. The dissolved matter then diffuses along the liquid phase and finally precipitates at the grain boundaries subjected to tension (Lofaj and Wiederhorn, 2009; Meléndez-Martínez and Domínguez-Rodríguez, 2004). Either the dissolution of the crystals or the diffusion of matter is the rate-controlling step, whichever is slower. In principle, the process is analogous to the solution-precipitation process during densification of silicon nitride.

Functional properties

Thermal conductivity

As a highly covalent compound, Si₃N₄ transports heat primarily by phonons at room temperature. The experimentally measured thermal conductivity of sintered polycrystalline Si₃N₄ is much lower than the predicted values (up to 450 W m⁻¹ K⁻¹ in the c-axis direction, see the Section “Properties”), and in most cases it lies between 60–90 W m⁻¹ K⁻¹ (Duan *et al.*, 2019; Kim *et al.*, 2017; Hu *et al.*, 2016; Zhu and Sakka, 2008). This is caused by the presence of GB phases with a rather low thermal conductivity (< 5 W m⁻¹ K⁻¹), and lattice defects in Si₃N₄ grains (impurity atoms, vacancies, dislocations, stacking faults, etc.), which can induce phonon scattering, resulting in the decrease of thermal conductivity. One of the main problematic impurities is oxygen, as the solution of oxygen in Si₃N₄ is relatively high and it generates vacancies at the Si sites in the Si₃N₄ lattice (Zhou *et al.*, 2015). Therefore, the use of a Si₃N₄ powder with a very low oxygen impurity content is essential for the preparation of Si₃N₄ with high thermal conductivities. Indeed, the highest ever reported value, experimentally measured for polycrystalline Si₃N₄, was 177 W m⁻¹ K⁻¹. This was obtained due to a significant reduction in the oxygen impurity content, as well as enhanced grain growth during post-sintering (Zhou *et al.*, 2015). Due to the intrinsic anisotropic thermal conductivity of Si₃N₄ grains, a highly anisotropic silicon nitride (~ 66%) can be prepared by texturing using HIP, in which the thermal conductivity is 155 and 52 W m⁻¹ K⁻¹ in the c-axis and a,b-axes directions, respectively (Watari *et al.*, 1999).

This all confirms that Si₃N₄ can reach almost as high thermal conductivity as AlN (~ 200 W m⁻¹ K⁻¹), while exhibiting significantly higher fracture toughness and strength when compared to AlN. Therefore, silicon nitride shows potential to replace AlN as a ceramic substrate for the next generation power devices.

Biological properties

Nowadays, silicon nitride is intensively investigated in the biomedical fields owing to its interesting biological properties. Reaction bonded Si₃N₄ was the first type of silicon nitride ever used in a human clinical trial as anterior lumbar interbody fusion in 1986 (Sorrell *et al.*, 2004). Since 2008, silicon nitride has been used as a fusion cage for arthrodesis of the cervical and thoracolumbar spine (Taylor *et al.*, 2010). At the present time, Si₃N₄-based materials are under development to be used as bearings components of prosthetic hip and knee joints, as spinal reconstruction devices and as inner parts of dental implants.

Silicon nitride is a bioinert, non-cytotoxic material, and its biocompatibility was already experimentally confirmed (Bal and Rahaman, 2012). Si₃N₄ is visible on plain radiographs as a partially radiolucent material and is non-magnetic, which allows an accurate view of the implant during surgical procedure and in postoperative evaluation on magnetic resonance imaging. Silicon nitride is more resistant to bacterial biofilm formation, colonization and growth (Gorth *et al.*, 2012), and has better osseointegration (Webster *et al.*, 2012), when compared to medical-grade PEEK (polyether ether ketone) and titanium implants. The wear rates of prototype Si₃N₄ total hip bearings against Si₃N₄ acetabular bearings are comparable to those of Al₂O₃-Al₂O₃ wear rates, which are the lowest of any orthopedic bearing (Bal *et al.*, 2009). Moreover, the in vivo environment should be even more favorable, since human synovial fluid is an excellent lubricant.

The current research in biological field is focused on the improvement of bioactivity of Si₃N₄ with the aim to promote faster and stronger silicon nitride osseointegration. This can be achieved either by coating of the Si₃N₄ surface with a hydroxyapatite layer (Precnerová *et al.*, 2015), or introducing a bioactive phase into the Si₃N₄ body, or using various surface treatments to produce a silica-rich or N-rich composition (Pezzotti, 2019; Hnatko *et al.*, 2020), which can influence the response of cells, tissues, and bacteria in vivo.

Introduction

Silicon nitride is a generic term that is used to describe a family of materials based on silicon nitride (Si_3N_4) but fabricated using different methods which give their names to the type of silicon nitride. Silicon nitride as a ceramic was first developed in the 1950s for use as thermocouple tubes, crucibles for molten metals and also rocket nozzles (Collins and Gerby, 1955). This type of material was formed by nitriding silicon powder compacts in the temperature range 1100–1450°C and was later termed reaction-bonded silicon nitride (RBSN) (Parr *et al.*, 1960).

Sintering of silicon nitride is quite difficult because self-diffusivity is low and species only become sufficiently mobile for sintering at temperatures where the decomposition of silicon nitride commences ($> 1850^\circ\text{C}$) (Riley, 2000). To promote densification, sintering additives, such as yttria and alumina (Sun *et al.*, 1998), are mixed with $\alpha\text{-Si}_3\text{N}_4$ powder which has layers of silica on its particle surfaces. The oxides react with this silica and some of the nitride itself at sintering temperatures to form an oxynitride liquid which promotes liquid phase sintering and densification by solution-diffusion-precipitation (Hampshire and Jack, 1981; Riley, 2000; Lange, 2006; Hampshire, 2009). The $\alpha\text{-Si}_3\text{N}_4$ dissolves in the liquid and is precipitated as $\beta\text{-Si}_3\text{N}_4$ which grows in the longitudinal direction as prismatic hexagonal rod-like crystals that eventually impinge on each other forming an interlocked microstructure. The liquid cools as an intergranular phase, usually a glass, according to the following:

Various rare earth (RE) oxides, with either alumina or MgO, have also been investigated (Becher *et al.*, 1998; Satet *et al.*, 2006; Becher *et al.*, 2010) as sintering additives and this allows the development of different types of microstructures and, hence, properties by modifying the chemistry of the sintering liquid phase. The types and amounts of additives used for sintering determine the nature and quantity of the resulting grain boundary phase which has a significant effect on materials properties. One significant milestone was the discovery of the SiAlONs (Jack, 1973, 1976; Thompson, 2002).

SiAlONs

SiAlONs are solid solutions based on the α - and β -silicon nitride structures in both of which the Si atoms lie at the center of Si-N₄ tetrahedra, joined at the corners to form 8-membered Si-N puckered rings which join in turn to form sheets perpendicular to the *c*-axis. In β -silicon nitride the sheets are stacked periodically ABABABAB, with large diameter channels parallel to the *c*-axis. In α the stacking sequence is ABCDABCD with the CD sheets rotated with respect to AB by 180° about the *c*-axis. The rotation creates 2 large interstices in the unit cell (in place of the channels in β) capable of accommodating metal cations.

β' -SiAlON is formed when oxygen (O^{2-}) replaces nitrogen (N^{3-}) in the $\beta\text{-Si}_6\text{N}_8$ structure while, at the same time, silicon (Si^{4+}) is replaced by aluminum (Al^{3+}) to maintain overall charge neutrality (Oyama and Kamigaito, 1971; Jack and Wilson, 1972). The β' -SiAlON solid solution composition is:

retaining the 6:8 metal: non-metal ratio of $\beta\text{-Si}_6\text{N}_8$, with *z* values in the range 0–4.2. The single-phase β' -sialon still requires a sintering additive such as Y_2O_3 in order to densify the ceramic (Ekström and Nygren, 1992). Microstructures are similar to $\beta\text{-Si}_3\text{N}_4$ with elongated hexagonal grains of β' -sialon but a reduced amount of intergranular glass phase.

α -SiAlONs (α') are based on the $\alpha\text{-Si}_{12}\text{N}_{16}$ unit cell with general composition (Hampshire *et al.*, 1978):

In α' -SiAlON, partial replacement of Si^{4+} by Al^{3+} occurs if, at the same time, charge compensation is effected by the accommodation of other ions, $\text{M} = \text{Li}^+, \text{Ca}^{2+}, \text{Y}^{3+}$ or rare earth lanthanide ions (RE^{3+}), in the two interstitial sites (*x*) in the unit cell. $x = m/v$ where *v* is the valence of the M cation, and *x* should be a value between 0.3 and 2 (the maximum value because of 2 interstitial sites per unit cell). As with β' , Y_2O_3 is used as a densification aid but also provides Y^{3+} ions for stabilization of α' . Other oxides where the cation can be accommodated in the α' -SiAlON structure are also used as sintering additives (Mandal, 1999).

Unlike Si_3N_4 , where $\beta\text{-Si}_3\text{N}_4$ is the main stable phase after sintering, the two SiAlON phases, α' and β' can coexist depending on the sintering additives used. Therefore, there are more variables to be used as design parameters for SiAlON ceramics and the amount of α' -SiAlON can be varied from 0% to 100% continuously and the type and amount of intergranular phase can also be modified by using mixed additives (Mandal *et al.*, 1999). These are usually combinations of CaO and two rare earth lanthanide oxides which allow more easier densification but on subsequent heat treatment, the final properties of the SiAlON ceramics can be tailored so that when high hardness is needed, α' -SiAlON content is increased and when higher toughness is required, then

Fig. 1 Phase Relationships in the SiO_2 - Si_3N_4 - Al_2O_3 system at 1700°C . After Jack, K.H., 1973. Nitrogen ceramics (17th Mellor Memorial Lecture). Transactions and Journal of the British Ceramic Society 72, 376–384.

additive chemistry is changed to give predominantly β' -SiALON (Mandal, 1999). These ceramics are already available as cutting tools or refractories and are being developed as wear parts (Çelik and Turan, 2021).

An initial challenge was how to represent phase relationships in complex systems involving nitrides and oxides. The phases formed when a mixture of alumina and normal silicon nitride powder is sintered cannot simply be represented on a binary Si_3N_4 - Al_2O_3 diagram since there is also SiO_2 present on the silicon nitride. Jack (1973) presented the ternary SiO_2 - Si_3N_4 - Al_2O_3 shown in Fig. 1 with the composition of β -SiALON along the Si_3N_4 - Al_2O_3 join. In addition to forming β -SiALON, another phase was discovered referred to as "X", so-called because its structure was unknown initially, which lies on a line between Si_3N_4 and mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$). Fig. 1 also shows an area marked O' which is $\text{Si}_2\text{N}_2\text{O}$ with partial replacement of Si and N by Al and O (Jack, 1973).

The x value given along the Si_3N_4 - Al_2O_3 join refers to the formula for β -SiALON which was thought to be correct at the time. Because x-ray analysis showed only one single-phase crystalline product, it was concluded, on the basis of limited chemical analyses, that the β' composition was:

$$\text{Si}_{6-3x/4}\text{Al}_{2x/3}\text{O}_x\text{N}_{8-x}$$

This formula satisfies valency balance requirements. However, further research (Jack, 1976; Lewis *et al.*, 1977) showed that compositions along the Si_3N_4 - Al_2O_3 join also contained some glass phase and that the β -SiALON phase range extended from Si_3N_4 towards Al_2O_3 consistent with the "z" formula:

$$\text{Si}_{6-z}\text{Al}_z\text{O}_z\text{N}_{8-z}$$

The question then was how to represent these more complex systems.

Representation of the Si-Al-O-N System

In view of the compositions which had been investigated, it was necessary to consider the complete (quaternary) Si_3N_4 - AlN - Al_2O_3 - SiO_2 system. Gauckler *et al.* (1975) and Jack (1976) both proposed adoption of the following representation of the Si-Al-O-N and related systems based on equivalent concentrations.

The Si-Al-O-N system has 4 component elements and so can be represented as a regular tetrahedron as shown in Fig. 2, each of the vertices of which represent one atom (or gram-atom) of the respective elements. It can be seen that the condensed phases: Si_3N_4 , AlN , Al_2O_3 , SiO_2 , lie at the corners of a quadrilateral, no two opposite sides of which are parallel. For example, Si_3N_4 (with 7 atoms in total) lies at a point $3/7$ along the edge from N to Si; AlN lies at a point $1/2$ along the edge from N to Al; Al_2O_3 lies at a point $3/5$ along the edge from Al to O; SiO_2 lies at a point $2/3$ along the edge from Si to O. This makes it inconvenient for plotting compositions and for representation of the phase relationships in the "normal" way for a phase diagram. A much simpler representation is obtained by expressing concentrations in "equivalents" instead of atoms or gram-atoms.

If each corner of the tetrahedron represents one equivalent of an element and, because one equivalent of any element or compound always reacts with one equivalent of any other species, the compositions of the phases Si_3N_4 , AlN , Al_2O_3 and SiO_2 , expressed in equivalents, are located at the mid-points of the edges of the tetrahedron as shown in Fig. 3 and the quadrilateral becomes a square.

A different approach gives the same conclusion. Effectively the composition of any condensed phase in the Si-Al-O-N system is determined by only two variables which can be plotted perpendicular to each other. This is the same as for reciprocal salt pairs (Findlay, 1927; Zernicke, 1955) which consist of two or three cations and two anions. The compositions are expressed in equivalent percent (eq.%) of cations and anions instead of atomic, molar or weight percentages (Gauckler *et al.*, 1975; Jack, 1976).

Thus, the four-component Si-Al-O-N system (Jack, 1976) is a square plane which has, as components, the oxides and nitrides of silicon and aluminum as shown in Fig. 4. In this system, it is convenient to let the bottom left hand corner of the square represent one mole of Si_3N_4 with 12 +ve and 12 -ve valencies. The other corners of the square represent Al_4N_4 , Al_4O_6 and Si_3O_6 . In going from left to right, 3Si^{4+} is gradually replaced by 4Al^{3+} and from bottom to top 4N^{3-} is replaced by 6O^{2-} . Any point in the square represents a combination of 12 positive and 12 negative valence units. The cations and anions are thus treated

Fig. 2 The tetrahedral representation of the Si-Al-O-N system. Adapted from Jack, K.H., 1976. Review: Sialons and related nitrogen ceramics. *Journal of Materials Science* 11, 1135–1158.

Fig. 3 The quaternary $\text{Si}_3\text{N}_4\text{-Al}_4\text{N}_4\text{-Al}_4\text{O}_6\text{-Si}_3\text{O}_6$ system in equivalent % is a square. Adapted from Tien, T.-Y., 1995. Chapter 4 – Use of phase diagrams in the study of silicon nitride ceramics In: Alper, A.M. (Ed.), *Phase Diagrams in Advanced Ceramics*. Elsevier, pp. 127–156.

separately. The concentrations can be expressed as equivalent percentages (eq.%) of either cations or anions as follows:

$$\text{equivalent percentage (eq.\%) Si} = (4[\text{Si}] \times 100) / (4[\text{Si}] + 3[\text{Al}]) \quad (2)$$

where [Si] and [Al] are, respectively, the atomic concentrations of Si and Al in any composition and 4 and 3 are their respective normal valencies.

$$\text{equivalent \% (eq.\%) Al} = 100 - \text{eq.\% Si} \quad (3)$$

For the anions:

$$\text{equivalent \% (eq.\%) of nitrogen} = (3[\text{N}] \times 100) / (2[\text{O}] + 3[\text{N}]) \quad (4)$$

where [O] and [N] are, respectively, the atomic concentrations of oxygen and nitrogen within any composition and 3 and 2 are their respective valencies.

$$\text{equivalent \% (eq.\%) oxygen} = 100 - \text{eq.\% N} \quad (5)$$

Fig. 5 The Si_3N_4 -AlN- Al_2O_3 - SiO_2 system at 1760°C. Adapted from Gauckler, L.J., Lukas, H.L., Petzow, G., 1975. Contribution to the phase diagram Si_3N_4 -AlN- Al_2O_3 - SiO_2 . *Journal of the American Ceramic Society* 58, 346–347.

Phases in the Si-Al-O-N System

The first diagram to use this approach for the Si_3N_4 -AlN- Al_2O_3 - SiO_2 system was presented by Gauckler *et al.* (1975) and a modified version of this is shown in Fig. 5. It gives the phases and their compositions after hot-pressing powder mixtures at 1760°C and is considered as a behavior diagram rather than an equilibrium phase diagram. The β' -SiAlON extends from the Si_3N_4 corner towards the composition $\text{Al}_2\text{O}_3\cdot\text{AlN}$ consistent with the “z” formula (Lewis *et al.*, 1977). A phase X_1 occurs in the region between $\text{Si}_2\text{N}_2\text{O}$ and mullite which is the same phase found by Jack (1973). Other phases labeled X_4 , X_2 , X_5 , X_6 , X_7 , were reported with compositions in the AlN-rich corner of the system.

Jack (1976) also used the approach of equivalent concentrations and published a different diagram for the Si_3N_4 - Al_4N_4 - Al_4O_6 - Si_3O_6 system at 1700°C shown in Fig. 6. As with the previous diagram by Gauckler *et al.* (1975), β' -SiAlON extends from the Si_3N_4 corner towards $\text{Al}_3\text{O}_3\text{N}$ with a range of compositions: $\beta'\text{-Si}_{6-z}\text{Al}_z\text{O}_z\text{N}_{8-z}$ where $z = 0$ is Si_3N_4 and the limit of solid solution is approximately $\beta'_{z=4.2}$. Silicon oxynitride, $\text{Si}_2\text{N}_2\text{O}$ also has a limited range of solid solution (marked O') with partial replacement of Si and N by Al and O. The liquid region at 1700°C in the SiO_2 -rich corner is quite extensive. Other phases in this system are X-phase and sialon polytypoids (8H, 15R, 12H, 21R, 27R and 2H⁰) with structures based on that of 2H wurtzite-type AlN (Roebuck and Thompson, 1977; Thompson *et al.*, 1983).

Sialon X-Phase

Sialon X-phase is triclinic with a unit cell containing, ideally, six $\text{Si}_3\text{Al}_6\text{O}_{12}\text{N}_2$ units. Its crystal structure consists of alternate chains of octahedra and tetrahedra, as in mullite, linked to form sheets that are stacked parallel and joined together by a network of tetrahedra, some units of which resemble those of the Si_6N_8 cell in $\beta\text{-Si}_3\text{N}_4$. The description of the X-phase as a “nitrogen mullite” is therefore not inappropriate. It melts congruently at 1725°C and its existence in “low” and “high” modifications is due to the very high incidence of stacking faults in the latter when it crystallizes rapidly from the supercooled melt (Thompson and Korgul, 1983).

Fig. 8 (a) The Jänecke prism representation of the M -Si-Al-O-N – M_yN_4 – M_yO_6 – Si_3N_4 – Al_4N_4 – Al_4O_6 – Si_3O_5 – system (M = 3rd cation), e.g., Mg, Ca, Y, RE (rare earth lanthanide). The distance, a , of any point P from the nitrides face represents the concentration ratio in equivalents of $O/(N + O) = [a/(a + b)]$; (b) Triangular vertical plane in the Jänecke prism with constant O:N ratio. Sides of the triangle are scaled in equivalent units of cations.

Sialon Polytypoids

Compositions in the Si-Al-O-N system between β' -sialon and the Al_4N_4 corner (see Fig. 6) show six phases with structures based on that of wurtzite-type AlN (Thompson *et al.*, 1983). They are a series of polytypoids, similar to the many polytypes of SiC (Kim and Malik, 2021) in that they exhibit changes in structural stacking in one dimension only, but differing from them in that the structures are directly related to their compositions M_mX_{m+1} , where m has values 4, 5, 6, 7, 9 and 11; the polytypoids have either hexagonal (H) or rhombohedral (R) unit cells described by the respective Ramsdell (1947) symbols 8H, 15R, 12H, 21R, 27R and $2H^d$, the latter being a disordered 2H structure. There are n double layers MX stacked along the c dimension of the unit cell, where n is the Ramsdell numeral and where $n_H = 2m$, $n_R = 3m$. Each block of m layers of wurtzite-type tetrahedra contains an inserted single layer of octahedra and, midway between these octahedral layers, metal atoms are shared between two adjacent layers of tetrahedra to give an MX_2 unit (Thompson *et al.*, 1983). Although x-ray methods do not distinguish between silicon and aluminum or between oxygen and nitrogen, there is little doubt that the layers of octahedra consist of aluminum coordinated by 6 oxygens.

Further Research on the Si-Al-O-N System

The Si_3N_4 – Al_4N_4 – Al_4O_6 – Si_3O_5 diagram based on research at the University of Newcastle upon Tyne, UK (Jack, 1976, 1986, 1991) has evolved over time. Fig. 6 at 1700°C does not include the 8H polytypoid (see above) which was confirmed by further research at higher temperatures as can be seen in Fig. 7 at 1800°C. It appears that the phase relationships change between 1700 and 1800°C. At both temperatures all of the polytypoid phases are in equilibrium with different β' -SiAlON compositions. The area of liquid phase becomes more extensive at 1800°C covering the X-phase composition and therefore the melting point of X-phase is below this temperature.

Any sialon composition can be produced in several ways. For example, β' -SiAlON with $z = 1$ may be prepared from different powder mixes, such as Si_3N_4 –AlN– Al_2O_3 , Si_3N_4 –AlN– SiO_2 , Si_3N_4 – SiO_2 –21R, etc., provided that allowance is made for the surface oxides that are always present on the nitrides. There are advantages in using preprepared polytypoids in place of AlN since they are less easily hydrolyzed and can be used as finer, more reactive powders to give a more homogeneous product (Jack, 1991).

Adapted from Jack, K.H., 1991. Sialons. In: Brook, R.J. (Ed.), Concise Encyclopedia of Advanced Ceramic Materials. Elsevier, pp. 411–416.

Representation of M-Si-Al-O-N Systems

Pressureless sintering of β -SiAlON can be achieved to near theoretical density but this still requires the use of an oxide additive such as MgO, Y_2O_3 or RE_2O_3 , where RE is a rare earth lanthanide element. To interpret the reactions and phase relationships that occur when a third cation is introduced, it is necessary to consider the representation of M-Si-Al-O-N systems, where M is a third cation with fixed valency. In this case, the apparent five components are effectively reduced to four and any composition is defined by only three independent variables. In the classification by Zernicke (1955) this is a “quaternary system of the third kind” and is represented by Jänecke’s triangular prism (Jänecke, 1907) shown in Fig. 8(a) for any M-Si-Al-O-N system. This is based on the Si_3N_4 - Al_4N_4 - Al_4O_6 - Si_3O_6 square of Fig. 4 with the third cation M with valency v_M in equivalent units in the third dimension:

$$\text{equivalent \% (eq.\%) of } M = (v_M[M] \times 100) / (4[Si] + 3[Al] + v_M[M]) \quad (6)$$

Fig. 11 The (α' -plane) or the Si_3N_4 - $4/3(\text{Al}_3\text{O}_3\text{N})$ - MN.3AlN plane where $\text{M} = \text{Y}^{3+}$ or RE^{3+} . The region of α' -sialon formation is based on data for $\text{Y}-\alpha'$ -SiAlON from Sun, W.Y., Tien, T.Y., Yen, T.S., 1991. Solubility limits of α' -sialon solid solutions in the system Si, Al, Y/N, O. *Journal of the American Ceramic Society* 74, 2547–2550. Adapted from Mandal, H., 1999. New developments in α -SiAlON ceramics. *Journal of the European Ceramic Society* 19, 2349–2357.

The front (right) triangular face of the Jänecke prism represents nitrides and the rear (left) face the oxides. Any vertical plane within the prism has a constant N:O ratio. As shown in Fig. 8(a), the distance, a , of any point P from the nitrides face represents the concentration ratio in equivalents of $\text{O}/(\text{N} + \text{O}) = [a/(a + b)]$. In the triangular vertical plane containing point P (Fig. 8(b)), the cation concentrations, in equivalents, are represented in the usual way for a ternary system. Any point in the prism, as with the Si-Al-O-N square, represents a combination of 12 positive and 12 negative valencies and so the edges of the prism can be scaled in valency units (Fig. 8(b)). The point P thus has a composition in valency units of:

$$\text{M}^{6+} + \text{Si}^{4+} + \text{Al}^{3+} + \text{O}^{6-} - \text{N}^{5-}$$

and in atomic units:

$$\text{M}_{6/_{\text{vm}}} \text{Si}_{1.0} \text{Al}_{0.67} \text{O}_{3.3} \text{N}_{1.8}$$

When Y_2O_3 is used as the sintering additive for Si_3N_4 or β' -SiAlON, a grain boundary glass is usually formed. However, a number of other crystalline phases can be formed either during sintering or by crystallizing the grain boundary glass phases in these ceramics. Fig. 9 shows the Y-Si-Al-O-N system (Jack, 1991) and the various crystalline phases that exist. In the Si_3N_4 - 4YN - $2\text{Y}_2\text{O}_3$ - 3SiO_2 sub-system (square back face of the prism), there are four Y-Si-O-N phases (Thompson, 1989): N-apatite, N-YAM, N-wollastonite and N-melilite and all of these phases extend into the Y-Si-Al-O-N prism. Not shown on this diagram is the range of compositions for α' -SiAlON containing Y.

Representation of M-Si-Al-O-N systems with α' -SiAlON

As outlined earlier, the general composition for α' -SiAlON (Hampshire *et al.*, 1978) is:

$$\text{M}_x\text{Si}_{12-(m+n)}\text{Al}_{(m+n)}\text{O}_n\text{N}_{(16-n)}$$

where M is Li, Mg, Ca, Y, Sc and rare earth lanthanides except La, Ce, Pr and Eu (Ekström and Nygren, 1992; Mandal, 1999). An important advantage of α' -SiAlONs is that the amount of intergranular phase is reduced by the transient liquid phase being absorbed into the α' -SiAlON crystal phase during sintering. However, complete densification can only be achieved either by hot pressing or HIPing.

α and β -sialon phases are completely compatible and α -sialon/ β -sialon composites have received increasing attention because of their easier fabrication compared with Si_3N_4 ceramics; by varying the starting composition using an appropriate mixture of nitrides and oxides and the heating and cooling cycle during sintering it was possible to vary the α/β phase ratio and particle morphology to tailor material properties for particular applications (Ekström and Nygren, 1992). Fig. 10 illustrates the relationship between α and β -sialon phase regions (Jack, 1991) on two planes in the M-Si-Al-O-N Jänecke prism with general compositions:

$$(\text{M,Si,Al})_6(\text{O,N})_8 \text{ and } \text{M}_x(\text{Si,Al})_{12}(\text{O,N})_{16}$$

The first one represents compositions with 3:4 stoichiometry (as for β) in which M cations substitute for Si or Al whereas the second has variable stoichiometry depending on the level of solubility (x) of the cation M into, for example, α -sialon with a fixed cation:anion ratio of $(\text{Si,Al}):(\text{O,N}) = 3:4$. This plane is referred to in many publications as the α' -plane (Jack, 1991; Shen and Nygren, 1997; Mandal, 1999; Rosenflanz and Chen, 1999).

Fig. 11 shows the α -SiAlON stability region on the $\text{M}_x(\text{Si,Al})_{12}(\text{O,N})_{16}$ (α' -plane) or more correctly the Si_3N_4 - $4/3(\text{Al}_3\text{O}_3\text{N})$ - MN.3AlN plane where $\text{M} = \text{Y}$ or RE (Shen and Nygren, 1997; Mandal, 1999; Rosenflanz and Chen, 1999). The extent of this region increases with decreasing size of the RE cation as well increasing temperature.

The phase composition and microstructure of α - and α - β -sialon ceramics are greatly affected by post sintering heat treatment procedures at lower temperatures (1300–1600°C) when rare earth oxides are used as sintering additives (Mandal *et al.*, 1993). The α -sialon phase is only stable at high temperatures and transforms to β -sialon plus other crystalline or vitreous phases. The ease with which this transformation proceeds decreases with increasing atomic number of the rare earth cation.

One advantage of α -SiAlONs is high hardness whereas fracture toughness is quite low relative to β -sialon (Mandal, 1999). The possibility to change the ratio of hard α -SiAlON to tough β -SiAlON by altering the composition makes α/β -SiAlON ceramics unique for applications in wear parts and cutting tools for metal machining operations. Because of the advancements in manufacturing technology and the possibility for close control of microstructure, novel α/β -SiAlON milling tools have been developed and commercialized (Çelik and Turan, 2021).

Introduction

SiAlONs, isostructural with Si_3N_4 , are ceramic alloys obtained by the replacement of silicon and nitrogen by aluminum, oxygen, and rare-earth (RE) cations in the crystal structure of silicon nitride (Rosenflanz, 1999; Izhevskiy *et al.*, 2000). While Si_3N_4 was discovered at the beginning of 20th century (Cao and Metselaar, 1991), partially dense Si_3N_4 ceramics were only developed in the 1950s for refractory applications such as thermocouple tubes, crucibles for molten metals and nozzles (Collins and Gerby, 1955). Dense silicon nitride was only developed in the 1960s and required the use of oxide additives to provide conditions for liquid phase sintering under applied pressure. The discovery of SiAlON ceramics was reported later in the early 1970s (Oyama and Kamigaito, 1971; Jack, 1973; Jack and Wilson, 1972). Due to their high strength, hardness, fracture toughness, corrosion and oxidation resistance, thermal shock resistance and refractoriness, Si_3N_4 and SiAlON ceramics are unique materials for applications such as cutting tools, bearings, turbochargers, engine valves and other wear resistant parts (Rosenflanz, 1999), used under aggressive conditions (Collins and Gerby, 1955; Sage and Histed, 1961; Parr, 1960). The properties and applications of both Si_3N_4 and SiAlON ceramics strongly depend on the technological development in effective densification techniques as well as starting powder quality. While high strength covalent bonds between Si^{4+} and N^{3-} give a remarkably high hardness to Si_3N_4 ceramics, self-diffusion of these ions makes these ceramics difficult to sinter without using sintering additives (Deeley *et al.*, 1961; Mitomo and Tajima, 1991). Therefore, the application of pressure assisted sintering techniques such as hot pressing (HP) (Yu *et al.*, 2017; Babini *et al.*, 1980; Bowen *et al.*, 1978; Kossowsky, 1973; Prochazka and Rocco, 1978; Wada *et al.*, 1999), gas pressure sintering (GPS) (Biswas and Riley, 2001; Hwang *et al.*, 1997; Mitomo *et al.*, 1990; Mitomo and Uenosono, 1992) and spark plasma sintering (SPS) (Wada *et al.*, 1999; Lukianova and Ivanov, 2018; Ratzker *et al.*, 2018; Lukianova *et al.*, 2017; Suganuma *et al.*, 2003) are required to obtain fully dense structures with minimum sintering additives. Thus, the solubility of Al and O as well as RE elements in the Si_3N_4 crystal structure brings a considerable advantage to SiAlONs over Si_3N_4 due to easier pressureless densification without diminishing high temperature properties (Rosenflanz, 1999).

Si_3N_4 has two major phases known as α and β , which have high hardness and toughness, respectively. Normally, α - Si_3N_4 is considered the low temperature form of Si_3N_4 (Cao and Metselaar, 1991) and a reconstructive transformation to β - Si_3N_4 occurs in the range 1400–1800°C (Cao and Metselaar, 1991; Evans and Sharp, 1971). Therefore, only the β modification exists in conventionally sintered Si_3N_4 ceramics. On the other hand, stabilization of α -SiAlON phase during sintering by proper selection of RE cations (Mandal, 1999; Ekström, 1992; Söderlund and Ekström, 1990) can be possible and is another advantage of SiAlONs compared to Si_3N_4 ceramics. Consequently, thermodynamically stable hard α -SiAlON (α') and tough β -SiAlON (β') phases can be present simultaneously, which means that optimum mechanical properties for a specific application can be designed by altering the α/β -SiAlON ratio (Kumar *et al.*, 2009).

The sintering oxides such as Y_2O_3 , Al_2O_3 , Yb_2O_3 , etc. react with nitrogen and SiO_2 , which always exists on the surface of Si_3N_4 powder particles, and form a liquid phase during sintering which is carried out in a N_2 gas atmosphere (Cinibulk *et al.*, 1992a; Ziegler *et al.*, 1987; Becher *et al.*, 1996). This liquid phase facilitates the densification and phase transformation during sintering and then solidifies as an amorphous phase around the Si_3N_4 grains (Drew and Lewis, 1974). It is well known that this amorphous phase starts to soften at temperatures around 1000°C, and deteriorates high temperature properties (Cinibulk *et al.*, 1992a; Lichvár *et al.*, 2007). Although crystallization of the grain boundary phase by a post sintering heat treatment, depending on the type and the composition of RE elements used as additives for Si_3N_4 , was reported in several studies (Lichvár *et al.*, 2007; Lee and Hilmas, 1989; Tsuge *et al.*, 1975; Weston *et al.*, 1978), the control of the crystallization of grain boundary phases is much easier for SiAlON ceramics thanks to high amounts of RE oxides. Therefore, SiAlON ceramics with superior high temperature mechanical and chemical properties can be fabricated by controlling grain boundary crystallization.

As stated above, SiAlONs are unique engineering ceramics, properties of which can be designed by controlling the α'/β' phase ratio, type of the RE additive system, “z” value of β -SiAlON (see below) indicating the solubility of Al_2O_3 in Si_3N_4 , and crystallinity of grain boundary phase. These parameters are shown schematically in Fig. 1. Here the aim is to explain and correlate the mechanical, thermal, and optical/electrical behavior of SiAlON ceramics with its corresponding structural parameters. Moreover, a brief section on applications is included in the last part to make clear structure-property-performance relationships in SiAlON ceramics.

Structure and Phases of SiAlON Ceramics

Si_3N_4 has two major polymorphs designated as α and β (Hardie and Jack, 1957) and a cubic spinel modification (γ) synthesized by application of high temperature and mechanical pressure above 15 GPa (Zerr *et al.*, 1999; Schwarz *et al.*, 2000). The crystallographic

Fig. 1 The structural parameters effective on the properties of SiAlON ceramics.

structure of α ($\text{Si}_{12}\text{N}_{16}$) and β (Si_6N_8) modifications are shown in **Fig. 2** (Legut *et al.*, 2014). β - Si_3N_4 is isostructural with Be_2SiO_4 (phenacite), in which oxygen and beryllium atoms are replaced by nitrogen and silicon, respectively (Hampshire, 2007). The total structure is formed by the combination of covalently bonded SiN_4 tetrahedra and each nitrogen at the corners is shared by three tetrahedra. The tetrahedra are linked with one edge parallel and one edge perpendicular to the (0001) plane in the hexagonal structure (Schwarz *et al.*, 2000). Both phases are characterized by planar structures parallel to the basal plane. Si-N planes in β - Si_3N_4 are stacked in a sequence of ABABAB..., with large diameter channels parallel to the c -axis, while the planes in α - Si_3N_4 repeat in every four layers stacked as ABCDABCD.... with the CD layers rotated with respect to AB by 180° about the c -axis. This blocks off the continuous channels resulting in two large interstices per unit cell capable of accommodating metal (Me) cations. Therefore, the length of the c -axis of α - Si_3N_4 is twice that of the β phase (Legut *et al.*, 2014).

SiAlONs exist as α -SiAlON (α') and β -SiAlON (β'), which are isostructural with α and β silicon nitride phases, respectively. β' -SiAlONs are obtained by the replacement of Si atoms by Al in the β - Si_6N_8 crystal structure. In order to maintain the charge neutrality, equivalent numbers of N should be substituted by O atoms. This replacement of Si and N with Al and O is illustrated by the general formula of $\text{Si}_{6-z}\text{Al}_z\text{O}_z\text{N}_{8-z}$, where " z " can be altered from 0 to 4.2 (Izhevskiy *et al.*, 2000; Mandal, 1999; Gauckler *et al.*, 1975; Jack, 1981; Ekström *et al.*, 1989). The stability region of β -SiAlON is narrow and lies on the Si_3N_4 -(Al_2O_3 , AlN) tie line in the phase diagram of Al_2O_3 - Si_3N_4 - SiO_2 -AlN given in **Fig. 3(a)** (Qin *et al.*, 2018; Bergman *et al.*, 1991; Mackenzie *et al.*, 1998). In the case of α -SiAlON, the stability region for α' is seen on the Si_3N_4 - $4/3(\text{Al}_2\text{O}_3$, AlN)-MeN.3AlN plane in the Me-Si-Al-O-N phase diagram (Janecke prism) shown in **Fig. 3(b)** (Me = Li, Mg, Ca, Y, RE) (Hampshire *et al.*, 1978; Thompson, 1989; Rosenflanz and Chen, 1999). The extent of this region increases with decreasing size of the Me cation (Rosenflanz and Chen, 1999; Shen *et al.*, 1997; Shen and Nygren, 1997) as well as increasing the temperature (Rosenflanz and Chen, 1999). The valency compensation is required due to the solubility of Me cations in the interstitial sites in the crystal structure. α -SiAlON, based on the α - $\text{Si}_{12}\text{N}_{16}$ crystal structure, is represented by the general formula:

where Me represents cations such as Mg, Ca, Y, Sm, Yb, etc., $x = m/v$ where v is the valency of the Me cation, and x should be a value between 0.3 and 2 (the maximum value because of 2 interstitial sites per unit cell). In α -SiAlON, the lattice strain is high due to the longer Al-N bonds ($\sim 1.87 \text{ \AA}$) replaced with Si-N bonds ($\sim 1.74 \text{ \AA}$), and this strain limits the value of m . Higher n values (more oxygen) in the formula also results in a tendency for α -SiAlON to be unstable and to formation of β -SiAlON (Mandal, 1999).

Mechanical Properties of SiAlON Ceramics

Ceramics have many advantages, such as high hardness, high wear resistance and chemical stability at high temperatures, over metallic materials for specific high temperature applications. However, they are susceptible to impact loads due to their strong ionic and/or directional covalent bonding. Although the brittle nature of ceramics limits their utilization, there are some methods

Reproduced from (a) Mackenzie, K.J., Sheppard, C.M., Barris, G.C., *et al.*, 1998. Kinetics and mechanism of thermal oxidation of SiAlON ceramic powders. *Thermochimica Acta* 318, 91–100. (b) Rosenflanz, A., Chen, I.-W., 1999. Kinetics of phase transformations in SiAlON ceramics: I. Effects of cation size, composition and temperature. *Journal of the European Ceramic Society* 19, 2325–2335.

to improve the resistance to propagation of a micro-crack by various mechanisms such as crack deflection, bridging, bowing, shielding etc. (Pelleg, 2014; Wachtman *et al.*, 2009). With the possibility to change the β and α phase content by slightly altering the composition, hardness and toughness of SiAlON ceramics can be designed for a specific application. While $\alpha\text{-SiAlON}$ is 40% harder than β -phase thanks to its 4 layers repetitive crystallographic structure (Ekström and Nygren, 1992), the rod-like grain morphology of $\beta\text{-SiAlON}$ grains (Satet *et al.*, 2006) gives the ability to deflect and to bridge a propagating crack as illustrated in Fig. 4, which shows the representative microstructure of an $\alpha/\beta\text{-SiAlON}$ ceramic. In the corresponding back-scattered electron (BE) SEM image, $\beta\text{-SiAlON}$ phase is seen as large dark gray rod-like grains, $\alpha\text{-SiAlON}$ phase appears as equiaxed and finer and light gray grains due to the partial solubility of high atomic number RE elements in the $\alpha\text{-Si}_3\text{N}_4$ crystal lattice. The sub-micron size white dots distributed throughout the structure are the grain boundary oxynitride crystalline/amorphous phase. When a crack starts to propagate along its path, it encircles the grain bridges. On the other hand, the frictional force between a grain and its surroundings may still provide a closure force on the crack surface. If grains are rod-like as in β , frictional bridging is remarkably effective for fracture resistance (Wachtman *et al.*, 2009). The crack bridging is expressed as the main toughening mechanism in alumina (Knehans and Steinbrech, 1982) and Si_3N_4 (Rödel, 1992; Becher, 1991) ceramics.

Fig. 4 A crack propagation profile in the microstructure of a representative α/β -SiAlON ceramic. Reproduced from Çelik, A., 2013. The Performance of SiAlON Ceramics on Drilling Operations of Carbon Fiber Reinforced Polymer Composites. (Doctoral thesis). Eskişehir: Anadolu University.

β - Si_3N_4 /SiAlON grains grow with the geometry of a hexagonal prism with pyramidal ends which are called basal planes. According to the periodic bond chain (PBC) theory (Krämer *et al.*, 1994), the growth perpendicular to the basal planes in a gas phase (porosity) is energetically favored and results in anisotropy. On the other hand, this model does not consider the atoms other than silicon and nitrogen adsorbed on the prismatic and basal planes and not applicable to the materials with high anisotropy (Satet *et al.*, 2006). In the case of Si_3N_4 or SiAlON, RE oxides, alumina and silica form an oxynitride grain boundary liquid phase which surrounds the nucleated grains during sintering. Results obtained by experimental studies explain the effect of grain boundary phase composition on the degree of anisotropic growth in Si_3N_4 /SiAlON ceramics and hence properties. Anisotropy is the result of the difference in growth rate of basal and prismatic planes (Hoffmann and Holzer, 2003) and fracture toughness increases with the increase in aspect ratio of the grains (Ye *et al.*, 2020) in which is related to the ionic radius of the RE element (Satet *et al.*, 2006; Becher *et al.*, 2008; Krämer *et al.*, 1993; Satet and Hoffmann, 2004; Satet and Hoffmann, 2005). For example, the dependency of anisotropic grain growth on RE addition is clearly shown by the fact that elongated grains with an aspect ratio of 8:1 can be obtained by La_2O_3 addition whereas relatively shorter grains (aspect ratio of 2:1) are observed by the addition of Lu_2O_3 (Becher *et al.*, 2008).

It is obvious that a bimodal microstructure consisting of elongated grains in a fine matrix results in toughening of Si_3N_4 and SiAlON ceramics because of crack deflection and crack bridging by larger elongated grains (Becher *et al.*, 1995). While β -phase already showed anisotropic growth as outlined above, further studies were undertaken to attempt to form α -SiAlON phase with elongated grains by (1) controlling grain boundary chemistry (Chen *et al.*, 2002; He *et al.*, 2011; Santos *et al.*, 2004; Zenotchkine *et al.*, 2003), (2) introducing seeds for external nucleation sites for elongated α grains (Kim *et al.*, 2000; Shuba and Chen, 2002; Zenotchkine *et al.*, 2002) and (3) application of heat treatment (Kurama *et al.*, 2002; Ye *et al.*, 2003; Ye *et al.*, 2004). Similar to the growth of β phase, the aspect ratio of α -SiAlON grains also increases with the ionic radius of RE elements in the composition. This can be attributed to the change in viscosity of the grain boundary glassy phase (Shelby and Kohli, 1990; Hampshire and Pomeroy, 2004) as well as the stability of α -SiAlON as a function of the dopant ion radius. If the RE element is too large to enter the interstitial sites in the α - Si_3N_4 structure, mass transfer and, therefore, driving force for grain growth becomes relatively low (Chen *et al.*, 2002). This results in large differences in the growth rates of basal and prismatic planes.

The utilizing of seed crystals with an exact composition is another method for obtaining elongated α -SiAlON grains. The number of elongated grains has a linear relationship with the amount of seed crystals. On the other hand, a similar relationship may not be observed in fracture toughness because of the reduction of the aspect ratio of the elongated grains with further seeding (Kim *et al.*, 2000). Moreover, a microstructure with very large elongated α -SiAlON grains gives rise to formation of stress points and reduction in strength of the overall material (Shuba and Chen, 2002). Therefore, the addition of seed crystals in small amounts (1–8 wt%) is suggested to optimize the mechanical properties.

A post heat treatment after sintering is generally performed to crystallize the amorphous grain boundary phase, but it also can increase α -SiAlON grain aspect ratio. On the other hand, crystallization of grain boundary phases can cause a considerable increase in interfacial bond strength for the systems containing excess amounts of rare-earth oxides. Thus, fracture toughness of SiAlON ceramics can decrease due to change in fracture mode from inter- to transgranular, which inhibits toughening mechanisms (Ye *et al.*, 2003). A similar effect is also observed for Al-O bonds replaced by Si-N (decreasing z value of β -SiAlON) (Becher, 1991; Sun *et al.*, 1998, 1999). The bond strength at the β -SiAlON-oxynitride glass interface is determined by the concentration of Al and O atoms. If z value increases up to 0.2, the number of strong chemical bonds at the interface increases rapidly, and the debonding becomes more difficult which results in an increase in the number of transgranular fractures. This leads to a further remarkable reduction in fracture toughness (Sun *et al.*, 1998). The further increase of z value from 0.3 to 1.1 results in a slight decrease of fracture toughness of SiAlON ceramics (Acikbas and Kara, 2017).

To conclude, room temperature mechanical properties of SiAlON ceramics strongly depend on (1) the α/β -SiAlON phase ratio, (2) the number and aspect ratio of elongated α and β -SiAlON grains in the microstructure, which is strongly influenced by the type

Fig. 5 Schematic illustration of the effect of various parameters on the fracture toughness of SiAlON ceramics.

of the RE elements and the bond strength of the SiAlON-grain boundary phase interface, on which the crystallinity of the grain boundary phase and z value of β -SiAlON are significant. A summary of these parameters controlling the mechanical properties of SiAlON ceramics is illustrated in Fig. 5.

Thermal Properties of SiAlON Ceramics

SiAlON ceramics are mainly utilized in applications at high temperatures such as cutting tools for high speed machining of metals, refractories for non-ferrous molten metals, wire drawing dies and welding pin locaters (De Faoite *et al.*, 2012). It is, therefore, critically important to determine the thermal properties of SiAlON ceramics. Within this section, the high temperature behavior of SiAlON ceramics and the key parameters are discussed.

Thermal Conductivity

As a successful cutting tool material for high-speed machining of cast irons and Ni-based high temperature alloys, the dispatch of heat from the SiAlON tool face is a critical issue since the excess heat accumulated on the surface results in temperature localization which in turn activates diffusion processes between tool and metal atoms and, thus, wear of the tool material. With a relatively simple structure in comparison to SiAlONs, the thermal conductivity of Si_3N_4 was reported as between $100\text{--}180 \text{ W m}^{-1} \text{ K}^{-1}$ (Hayashi *et al.*, 2001; Zhu *et al.*, 2006, 2007; Yokota and Ibukiyama, 2003b; Kim *et al.*, 2017) by experimental results, while it can

theoretically reach $170 \text{ W m}^{-1} \text{ K}^{-1}$ and $450 \text{ W m}^{-1} \text{ K}^{-1}$ along a- and c-axis directions, respectively (Hirosaki *et al.*, 2002). The reasons for much lower thermal conductivity of Si_3N_4 ceramics than the theoretical values were attributed to factors causing the scattering of phonons (lattice vibrations) such as the presence of amorphous grain boundary phases with very low thermal conductivity ($1 \text{ W m}^{-1} \text{ K}^{-1}$) (Zhu *et al.*, 2007; Kim *et al.*, 2017; Kitayama *et al.*, 1999), impurities, vacancies, etc. (Kitayama *et al.*, 2000; Yokota and Ibukiyama, 2003a).

SiAlONs are solid solutions obtained by the introduction of different atoms into the α and β Si_3N_4 crystal structures. Therefore, it is normal to see much lower thermal conductivity for SiAlON ceramics due to these foreign atoms as well as the presence of both α and β phases together. As with the mechanical properties, the thermal conductivity in SiAlON ceramics strongly depends on the amount and composition of each phase (α , β and grain boundary phase) and microstructural properties such as grain size, amount of grain boundary phase, grain size distribution and elongation of grains. The ratio of α/β -phases is one of the most important factors affecting the thermal conductivity. An inverse relationship between α -SiAlON phase content and thermal conductivity of an α/β -SiAlON composite was reported (Liu *et al.*, 1995). This is related to the differences in crystallographic structures of α and β phases. In the β -SiAlON structure, SiN_4 tetrahedra are linked together to form tunnel (channel) structure (Fig. 2). On the other hand, this tunnel structure does not exist in α -SiAlON due to the presence of the additional glide plane, which behaves as a defect (Kohatsu and McCauley, 1974) and results in the formation of the interstitial sites in which the RE and other cations are accommodated. Thus, the higher degree of asymmetry and complexity of the crystal structure of α -SiAlON reduces the phonon mean free path (Liu *et al.*, 1995). Since different RE elements from Lu^{3+} to Nd^{3+} (Redington *et al.*, 1991) can be incorporated into the α -SiAlON structure, the thermal conductivity of α -phase stabilized with different additives is expected to show some minor variation. The α -SiAlON ceramics prepared by utilizing single dopants and smaller cations such as Lu^{3+} , Yb^{3+} , etc. have higher thermal conductivities due to less phonon scattering by smaller elements and the simplicity of the crystal structure (Kushan *et al.*, 2007).

The thermal conductivity of Si_3N_4 ceramics is very sensitive to lattice oxygen content and remarkably reduces even at low oxygen concentrations ($z < 0.03$) (Kusano *et al.*, 2014). Similarly, the z value of β -SiAlON is the other main determinant in reducing thermal conductivity, apart from α -phase content and the type of RE elements. In commercial α/β -SiAlON ceramics, β -phase generally has a z value in the range ~ 0.2 -1 whereas $z = 0$ for Si_3N_4 ceramics. The increase in lattice defects with the replacement of Al-O bonds for Si-N bonds results in more phonon scattering and, accordingly, lower thermal conductivity (Yi *et al.*, 2014; Dong *et al.*, 2012). Finally, the crystallization of grain boundary phase is also an influencing factor on thermal conductivity of SiAlON ceramics. Generally, amorphous materials show lower thermal conductivity and diffusivity than crystalline counterparts in a specific composition because of higher phonon scattering. Therefore, crystallization of the grain boundary phase by application of post sintering heat treatment results in slightly higher thermal conductivity (Bentsen *et al.*, 1984).

Thermal Shock Resistance

Ceramics are susceptible to catastrophic fracture under severe thermal transient conditions. The ability to survive against sudden temperature differences is defined as "thermal shock resistance" (Li *et al.*, 2015). In simple terms, the thermal shock resistance parameter, R' , is the maximum allowable temperature difference ΔT_c to which a ceramic can be subjected without initiation of fracture:

$$R' = \Delta T_c = \frac{\sigma_f(1 - \nu)}{\alpha E} k \quad (1)$$

It is controlled by the fracture strength (σ_f), thermal expansion coefficient (α), elastic modulus (E) and thermal conductivity (k) of the material (Manson and Smith, 1955). Increase in σ_f and k and decrease in α improves the thermal shock resistance of brittle ceramics. The thermal shock resistance of SiAlONs is remarkable thanks to their relatively high fracture strength and thermal conductivity among structural ceramics and is of great importance especially for refractory and cutting tool applications (Pettersson *et al.*, 2002). However, there are limited number of studies performed to analyze the effect of structural parameters on the thermal shock resistance of monolithic SiAlON ceramics (Li *et al.*, 2015; Pettersson *et al.*, 2002; Lee *et al.*, 1989; Liu *et al.*, 2010; Pettersson *et al.*, 2001; Ye *et al.*, 2010; Zheng *et al.*, 2012). The thermal shock resistance of β -SiAlON is strongly influenced by microstructural and mechanical properties. The change in fracture mode from transgranular to intergranular with decreasing z value results in better thermal shock resistance. Moreover, utilizing higher quantities of sintering additives and higher sintering temperature results in formation of more elongated β grains, which in turn gives higher fracture toughness β -SiAlON ceramics and, therefore, higher thermal shock resistance (Pettersson *et al.*, 2002). For quenching cycles in which the temperature difference is above 1000°C , the thermal oxidation can provide a positive effect on the closure of the thermal cracks. As a result of the oxidation of SiAlON grains, viscous products can fill the tip of the micro-cracks and make the propagation more difficult (Liu *et al.*, 2010).

Another approach is to reinforce SiAlON ceramics in terms of fracture toughness by the addition of other ceramics in particulate (Tian *et al.*, 2011; Acikbas *et al.*, 2014) or platelet shape (Tian *et al.*, 2019). For example, addition of 25 wt% TiN to an α/β -SiAlON improves the thermal conductivity and fracture toughness as well as thermal shock resistance of the matrix considerably (Acikbas *et al.*, 2014).

Turan, D., Uludag, A., Turan, S., 2019. Effect of heat treatment on the creep behavior of α/β SiAlON sintered with multication oxide sintering additives. *International Journal of Applied Ceramic Technology* 16, 404–409.

Creep Behavior of SiAlON Ceramics

Creep is defined as time dependent deformation of a material under stress at high temperature and is considered a good representation for high temperature behavior of SiAlON ceramics utilized especially as tools for metal machining operations. The creep tests are generally performed by the application of static load on the material in tension or compression at high temperature. At the end of the test, a typical strain-time graph with three distinct regions is obtained. In the first region (primary creep), strain rate gradually decreases. Then, the rate becomes constant in a secondary creep region, and, finally, a rapid increase is observed in the tertiary creep region prior to fracture (Fox and Hellmann, 2008). In the case of Si_3N_4 and SiAlON ceramics, the tertiary creep region is not observed due to the brittle nature of Si_3N_4 based ceramics (Menon *et al.*, 1994; Luecke *et al.*, 1995; Wereszczak *et al.*, 1999).

The creep resistance of SiAlON ceramics is controlled by microstructural features such as α/β phase ratio, morphology of the grains, grain size, grain boundary phase composition and structure (Fox and Hellmann, 2008; Fox *et al.*, 2006). An improved creep resistance of α -SiAlON can be obtained by reducing the grain boundary phase via incorporation of additive elements into the crystal structure (Rosenflanz, 2002). On the other hand, β -SiAlON phase shows better creep resistance than α -SiAlON thanks to its more elongated grain structure, which hinders grain boundary sliding (Wereszczak *et al.*, 1998). While the effect of grain size is less pronounced, the chemistry of the grain boundary phase is a much more influencing factor on the creep performance of Si_3N_4 -based ceramics (Wiederhorn *et al.*, 2004).

The type of RE oxides used for liquid phase sintering of SiAlON ceramics has a strong effect on the creep resistance of SiAlON ceramics since it determines the viscosity of the grain boundary phase at high temperatures. The smaller the cation, the higher the viscosity, which results in reduced grain boundary sliding and, thus, improved creep resistance. The effect of viscosity of the grain boundary phase can also be seen in the strain rate-time curve in which a slowly decreasing rate rather than a steady-state creep rate is generally observed for Si_3N_4 /SiAlON ceramics. The decreasing rate is attributed to the gradual increase in viscosity of the grain boundary phase due to the partial crystallization and oxidation during creep (Cinibulk *et al.*, 1992b). Accordingly, the crystallization of the grain boundary phase is as important as grain boundary composition on creep resistance. A good example is the differences in creep behaviors of as-sintered (Turan *et al.*, 2019) and subsequently heat treated α/β -SiAlON ceramic (Turan *et al.*, 2019) prepared

Fig. 7 Cross-section scanning electron micrographs of (a) Y- and (b) Er-doped α/β -SiAlON ceramics oxidized at 1350°C for 2 h. Reproduced from Çelik, A., 2019. Oxidation behavior of Y_2O_3 and Er_2O_3 -doped- α/β -SiAlON ceramics. Akademik Platform Mühendislik ve Fen Bilimleri Dergisi 7, 381–388.

with Y^{3+} as the main dopant and small amounts of Sm^{3+} and Ca^{2+} . The as-sintered ceramic has a considerable amount of crystalline grain boundary phase in the form of melilite ($Ln_2Si_{3-x}Al_xO_{3+x}N_{4-x}$) as shown in Fig. 6(a). Therefore, the creep resistance of this ceramic is observed to be much higher than Si_3N_4 as shown in Fig. 6(b). After a post heat treatment performed at 1600°C for 2 h, the crystallization of melilite phase at the triple pockets and grain boundaries is enhanced which provides an improvement in creep resistance (Uludağ and Turan, 2011; Turan et al., 2019). The stress exponent (n) gives an indication of creep mechanisms in SiAlON ceramics such as viscous flow, grain boundary sliding, cavitation, etc. and was determined as 1.6 and 1.4 for as-sintered and heat treated SiAlON ceramics, respectively, as shown in Fig. 6(c). These values show that the main creep mechanism for SiAlON under bending stress is grain boundary sliding. The activation energies indicating the creep resistances were also calculated as 692 kJ/mol and 708 kJ/mol for the corresponding ceramics as shown in Fig. 6(d).

Oxidation Behavior and Chemical Stability of SiAlON Ceramics

Oxidation is one of the main problems not only for SiAlON ceramics, but also for the other non-oxide ceramics utilized in high temperature applications under normal atmospheric conditions. It is well known that the oxidation resistance of SiAlON ceramics depends on the individual parameters influencing the properties of α , β and grain boundary phases. In addition to these parameters, it should be noted that insufficient densification after sintering also has a detrimental effect on the oxidation resistance (Hou et al., 2012). Only 2% lower densification of β -SiAlON ceramics results in a considerable reduction in oxidation resistance. For β phase, the z value in the general formula of $Si_{6-z}Al_zO_{2.5}N_{8-z}$, indicating the solubility of Al and O atoms in crystal structure of β - Si_3N_4 , is known to have a significant effect on the properties including oxidation resistance. The formation of crystalline and/or amorphous oxide products as a result of oxidation reactions is affected by the amount and viscosity of the grain boundary phase and also the z value of β -SiAlON (Lewis and Barnard, 1980; Pomeroy and Hampshire, 1985). While the oxidation kinetics for SiAlON ceramics generally obey a parabolic rate law (Shimada et al., 1998; Singhal, 1976), some deviation occurs with the change in z value of β -SiAlON which directly determines the type of oxidation products. The increase in the crystallization of oxide products with increasing z value can be assumed as a positive effect due to the formation of a more durable layer against inward diffusion of oxygen, but this layer also prevents outward diffusion of gas products (especially N_2), which results in formation of bubbles in the oxide scale and, thus, discontinuity. After formation of bubbles and cracks in the oxide scale, the diffusion becomes severe again. Consequently, the oxidation kinetic is slower for lower z values due to the formation of a more continuous protective oxide scale (Yi et al., 2010).

The oxidation resistance of α -SiAlON is higher than that of β -phase due to lower amount of grain boundary phase in the final microstructure as a result of incorporation of dopant cations into the α -SiAlON structure. The formation of cristobalite and mullite in the oxide scale is independent from the RE elements for α -SiAlON ceramics. These two crystalline phases are good protective barriers for inward diffusion of oxygen in the oxide layer and outward diffusion of dopants through grain boundaries. However, after crystallization of rare-earth containing silicates and aluminates, the protective nature of the scale is changed, unavoidably. The types of crystalline phases formed is the main determinant of the oxidation resistance of α -SiAlON ceramics and this is controlled by the dopants (Yu et al., 2004; Nordberg et al., 1998; Çelik, 2019). It is possible to conclude that improved oxidation resistance can be obtained for α -SiAlON ceramics containing rare-earth cations such as Y^{3+} , Yb^{3+} , Er^{3+} , etc., which leave oxygen-rich grain boundary phases after sintering (Bergman et al., 1991; Mackenzie et al., 1998). These ceramics experience silicate crystallization in the oxide scale during oxidation reactions. If the oxide scale consists mainly of aluminate crystals, as in the case of Sm^{3+} and Nd^{3+} , then the oxide scale also has large bubbles, indicating N_2 gas evaporation from oxidation of the grain boundary phase, which is generally nitrogen-rich melilite. The easy removal of gas bubbles also indicates a much lower viscosity silicate liquid phase is present (Mackenzie et al., 1998). Representative scanning electron micrographs of Y- and Er-doped α/β -SiAlON ceramics after oxidation tests performed at 1350°C for 2 h are shown in Fig. 7 (Çelik, 2019). The larger amount of bubble formation for the Er-doped sample is attributed to the higher degree of crystallization of the grain boundary phase in the form of melilite. The

Fig. 8 Schematic illustration of the structure of the diffusion interface between SiAlON and Inconel 718 alloy. Reproduced from Çelik, A., 2018. Dopant-dependent diffusion behavior of SiAlON ceramics against Inconel 718 superalloy. *Ceramics International* 44, 17440–17446.

utilization of alkali and alkaline earth oxides rather than RE oxides gives rise to formation of low eutectic liquids and foam-like oxide scales on the surface of the oxidized ceramics. Due to the rapid diffusion of oxygen and other elements through this foam-like scale, a severe oxidation of α -SiAlON ceramics doped with alkaline oxides is observed (Yu *et al.*, 2004; Liu *et al.*, 2017).

Because SiAlONs are generally used as refractory parts and cutting tools in metallurgical and machining industries, respectively, the chemical stability of these ceramics against metals at high temperatures needs to be taken into consideration. When Si_3N_4 based ceramics are in contact with ferrous molten alloys such as steel, solid solution of Si in Fe occurs and various silicides, Fe_3Si , Fe_5Si_3 and FeSi are formed as a result of severe corrosion (Shimoo *et al.*, 1997; Křestán *et al.*, 2007). A similar diffusion-based reaction between SiAlON and steel is also observed due to the high tool-chip contact length in machining operations of steel with SiAlON cutting tools (Buljan and Wayne, 1989). Therefore, chemical resistance is one of the main parameters for tool selection for machining of alloys containing high amounts of Fe. The other class of metals, which cannot be machined with SiAlON tools is titanium and its alloys due to chemical incompatibility of highly reactive Ti and the elements present in SiAlON tools (Tunckan *et al.*, 2013, 2019). In this case, the formation of complex Ti-Si-N compounds at the interface inhibits the utilization of SiAlON ceramics for machining of Ti-based alloys. The chemical stability of SiAlON tools also plays an important role in high speed machining of Ni-based superalloys. Since there are too many elements available in both SiAlONs and superalloys, the diffusion process is quite complicated. In Fig. 8, a schematic illustration of the interface between a SiAlON and Inconel 718 alloy is shown in which three distinct layers are formed because of severe competitive diffusion from each side (Çelik, 2018). The thickness of the diffusion zone depends more on the crystallinity of the grain boundary phase rather than parameters related to the α and β phases such as α/β ratio, z value, aspect ratio, etc.

Optical Properties of SiAlON Ceramics

From the simultaneous discovery in Japan (Oyama and Kamigaito, 1971) and in England (Jack and Wilson, 1972) of β -SiAlON and that of α -SiAlON (Hampshire *et al.*, 1978), to date SiAlON ceramics are well known as impressive materials for structural applications due to their unique thermo-mechanical properties controlled by their structural parameters. Chronologically, β -SiAlON was first obtained as optically transparent with 50% of infrared transmittance (Mitomo *et al.*, 1982), and then absorption spectra of RE doped α -SiAlONs were reported at the end of 1990s (Shen *et al.*, 1997; Karunaratne *et al.*, 1996). The factors which are effective for the optical transmission of polycrystalline materials are divided into two categories: (1) intrinsic factors such as bond strength and vibrational energy of the bonds and (2) extrinsic factors such as porosity, impurities, grain boundary phases, etc. (Fox, 2002). Therefore, obtaining full densification after sintering, reducing the amount of grain boundary phases as much as possible and keeping the microstructure uniform and more equiaxed are necessary to eliminate the external factors (Joshi *et al.*, 2012). Besides equiaxed grain shape, selective dissolution of RE ions from the grain boundary phase into the crystal structure gives a considerable advantage to α -SiAlON ceramics in terms of reduction of grain boundary phase and makes it a suitable material for applications in which optical transparency is required. In α -SiAlON ceramics, distribution, size and shape of grains, amount of secondary amorphous and crystalline phases are the characteristic factors which affect optical transmittance. These factors are directly related to the type of metal cation in SiAlON systems (Su *et al.*, 2004b). In contrast to improved fracture resistance by using the large RE elements for elongation of α and/or β -SiAlON grains, the aim here is to obtain more equiaxed grains and stabilization of α phase with smaller size cations (Joshi *et al.*, 2012; Su *et al.*, 2004b). Moreover, sample thickness (Su *et al.*, 2004c), distribution of rare earth elements in α -SiAlON grains (Su *et al.*, 2004a), and carbon contamination arising from

the sintering environment during hot pressing (Chen *et al.*, 2005), also have considerable effects on the transparency of α -SiAlON ceramics.

Phosphors are high purity inorganic materials that emit light when exposed to various excitation sources such as photons, electrons or an electrical field. These materials are used as field emission displays, fluorescent lamps, cathode-ray tubes, etc. (Blasse and Grabmaier, 1994; Xie *et al.*, 2002). A luminescent material is composed of a host lattice and small amounts of impurity ions with a luminescent property (Joshi *et al.*, 2012). The inorganic phosphors based on RE doped oxynitride ceramics are popular as host materials due to their nontoxicity, thermal stability, and luminescence properties (Höppe *et al.*, 2000; Uheda *et al.*, 2000; Jansen and Letschert, 2000). Among these oxynitrides, hexagonal α -SiAlON is one of the most attractive materials for optical luminescence applications due to its suitable crystal structure for anti-stokes photoluminescence compared with cubic crystals (Krämer *et al.*, 2004; Suyver *et al.*, 2006; Joshi *et al.*, 2015). On the other hand, detailed TEM investigations revealed that not only α -phase but also β -SiAlON has the ability to incorporate some RE elements, such as Yb and Ce, in its crystal structure (Yurdakul *et al.*, 2011). This gives potential applications for α/β -SiAlON ceramics as luminescent materials in which the emission color depends on the luminescence cation. The yellow-emitting Ca-SiAlON:Eu²⁺ is attracting great attention because it can be used to create warm white LEDs (Blasse and Grabmaier, 1994; Xie *et al.*, 2016, 2006, 2004). The green-emitting Mg-SiAlON:Er³⁺ phosphors have potential applications in windows for solar cells (Yurdakul *et al.*, 2011).

Electrical Properties of SiAlON Ceramics

The electrical conductivity of SiAlON ceramics is very low due to absence of charge carrier free electrons and/or ions (Thorp and Sharif, 1976; Ukyo *et al.*, 1979; Mitomo and Uemura, 1981). Therefore, the application of SiAlON ceramics related to electrical properties is restricted to insulator materials. However, there is still a strong demand for electrically conductive SiAlON ceramics because of their outstanding thermo-mechanical properties which make SiAlONs suitable for a wide range of electrical applications such as glow-plugs, heaters, igniters, etc. (Ayas *et al.*, 2008). Although much higher electrical conductivity can be obtained by doping of α -SiAlON ceramics with Li (1000 times higher than that of pure SiAlON) (Sharif *et al.*, 1981), the general approach to improve the conductivity of SiAlONs is the addition of conductive secondary phases such as TiN (Ayas *et al.*, 2008; Bellosi *et al.*, 1992), TiCN (Ayas and Kara, 2011), SiC (Kim *et al.*, 1998; Yamada and Kamiya, 1999) as well as graphene (Baskut *et al.*, 2018; Baskut and Turan, 2020). A good example for the efficiency of different graphene-nanoplatelets (GNPs) (GNP1-GNP4) as electroconductive reinforcement phases is given in Fig. 9 (Baskut and Turan, 2020). While the electrical conductivity of pure SiAlON ceramic is around 10^{-9} S m⁻¹, the conductivity of the ceramic composite is drastically increased with the addition of only 1.5 wt% GNPs. It is also observed in Fig. 9 that the SiAlON-GNPs composites have a remarkable anisotropy in electrical conductivity values due to the vertical alignment of GNPs to the pressing direction during spark plasma sintering (SPS).

Applications of SiAlON Ceramics

The application of SiAlON ceramics is increasing gradually due to technological progress on the synthesis of high purity raw starting powders as well as efficient sintering techniques such as hot pressing, gas pressure sintering and spark plasma sintering, etc. Fig. 10 shows images of some structural SiAlON products used mainly as relatively low temperature wear resistant parts (attritor

Fig. 10 Representative images of SiAlON wear parts, solid milling cutters and turning inserts used in structural applications (photo courtesy of MDA Advanced Ceramics Co.).

mill arms for fine milling of ceramic slurries, pipe bending rollers, etc.) and cutting tools for metal machining operations. The possibility to change the ratio of hard α -SiAlON to tough β -SiAlON by altering the composition makes α/β -SiAlON ceramics unique for wear parts utilized at relatively low temperature applications. The wear of SiAlON ceramics in such applications is directly related to the tribological behavior of these materials which has been the subject of various research investigations (Kumar *et al.*, 2009; Jones *et al.*, 2003; Kurama *et al.*, 2009; Sun *et al.*, 2017). The general results in these studies proved that the amount of β -SiAlON phase, the crystallization of grain boundary phase and z value are critical factors influencing the total amount of wear. The difficulties of manufacturing large parts with complicated geometries (Fig. 10) is the major problem for commercializing of SiAlON wear resistant components.

The main utilization of SiAlON ceramic inserts is the high speed turning of cast irons at cutting speeds up to 1000 m/min. (Mandal *et al.*, 2003; Bitterlich *et al.*, 2008; Tu *et al.*, 2016; Bitterlich and Friederich, 2007; Acikbas *et al.*, 2012). The application of high cutting speeds is related to the discontinuous chip formation due to the relatively brittle nature of cast iron during cutting operations. On the other hand, use of SiAlON inserts for turning of ferrous metals is constrained by the ductility of the metal part. Therefore, steels as a more ductile version of cast iron cannot be machined with SiAlON inserts because of the high chemical interaction between tool and workpiece at high cutting speeds. Since the oxidation resistance and chemical stability of SiAlON ceramics can be improved by adjusting the optimum z value of β -SiAlON and the amount of α -SiAlON in α/β -SiAlON ceramics, it is possible to create successful turning/milling inserts for high speed machining of Ni-based high temperature alloys (Hao *et al.*, 2017; Sun *et al.*, 2020; Tian *et al.*, 2013; Zheng *et al.*, 2010). Because of the advancements in manufacturing technology and the possibility for close control of microstructure, novel α/β -SiAlON milling tools have been developed and commercialized (Fig. 10). The key point in this application is to increase the cutting zone temperature intentionally by performing the operation at ultra-high cutting speeds (above 600 m/min.) to soften the superalloy part. As a result of softening of the workpiece, the mechanical stress acting on the tool is reduced, and catastrophic fracture is prevented (Çelik *et al.*, 2017; Finkeldei *et al.*, 2019; Dang *et al.*, 2020; Ming *et al.*, 2020; Huang *et al.*, 2020). Since high temperature is required in the cutting zone for this mechanism, SiAlON tools can only be applicable in machining operations of deformable metallic materials in which the loads acting on the tool face are more uniform. The machining of non-metallic anisotropic materials such as fiber reinforced polymer composites is not possible with SiAlON tools because of the cyclic cutting loads resulting from the anisotropy, which causes propagation of microcracks and, therefore, severe microchipping of the tool cutting edge (Çelik *et al.*, 2015a,b).

Apart from refractory parts for metallurgical applications, SiAlON ceramics are being developed as optical luminescence components such as light emitting diodes (LEDs), fluorescent lamps, X-ray detectors, etc. The relative performance of an Er-doped α -SiAlON ceramic as a high temperature sensor was investigated and superior thermal and chemical stability was attained compared with chalcogenide and fluoride glass-based optical temperature sensors; a maximum operating temperature of 1273K, the highest temperature measurement via FIR technique in optical thermometry, was achieved (Kshetri *et al.*, 2020). Moreover, the biocompatibility of SiAlON ceramics has also been examined in a series of studies (Li *et al.*, 2020; Xie *et al.*, 2019; Zhang *et al.*, 2020a,b). With promising

results from these studies on the compatibility with bone-cell cultures, SiAlON based ceramics can be highlighted as potential bone restorative bioceramics in the near future.

Phase Equilibria and Crystal Chemistry

Substitution of nitrogen for oxygen in Al_2O_3 or, conversely, substitution of oxygen into AlN stabilizes new phases with significantly different crystal structures and symmetry (space group): $\alpha\text{-Al}_2\text{O}_3 = R\bar{3}c$, AlON = $Fd\bar{3}m$, and AlN = $P6_3mc$ – rhombohedral, cubic, and hexagonal, respectively. AlON can be thought of as a nitrogen-stabilized cubic aluminum oxide. It has many properties comparable to $\alpha\text{-Al}_2\text{O}_3$, but because of its cubic crystal structure, fully dense, polycrystalline bodies can be completely transparent if processed properly (McCauley and Corbin, 1979). Other properties, like dielectric loss tangent, can be extremely low because of the lack of thermal expansion-induced residual strain at grain boundaries. AlN is an intriguing material because of its theoretical thermal conductivity of about $320 \text{ W m}^{-1} \text{ K}^{-1}$ at room temperature – extremely high for a dielectric material and comparable or higher than many metals. Excellent reviews for AlN can be found in Dugger (1975), Sheppard (1990), and Prohaska and Miller (1990); for AlON in Corbin (1989); and for polycrystalline α -alumina in Munro (1997).

Figure 1 illustrates the proposed phase-equilibrium diagram for the pseudobinary Al_2O_3 –AlN composition join determined experimentally by McCauley *et al.* (1988). In a series of papers (Willems *et al.*, 1992a,b; Dumitrescu and Sundman, 1995; Qiu and Metselaar, 1997), the thermodynamics of AlON have been worked out and the phase relations calculated, confirming the main aspects of the experimental diagram. Tabary and Servant (1998) have also reassessed the phase relationships in this system. Fukuyama *et al.* (1999), using plasma arc melting to produce AlON powder, seem to have confirmed the vapor–liquid relationship in the extreme temperature region. Besides the three primary phases, there are also many intermediate phases. Among these are the following.

AlON– Al_2O_3 region:

- $13\text{Al}_2\text{O}_3:1\text{AlN} = \phi\text{-Al}_2\text{O}_3$ (Michel, 1972)
- $9\text{Al}_2\text{O}_3:1\text{AlN} = \delta\text{-Al}_2\text{O}_3$ (Long and Foster, 1961; Lefebvre *et al.*, 1972; Tabary and Servant, 1999b)
- $10\text{Al}_2\text{O}_3:2\text{AlN} = \zeta\text{-Al}_2\text{O}_3$ or $\phi'\text{-Al}_2\text{O}_3$ (Long and Foster, 1961; Michel, 1972); $\text{Al}_{22}\text{O}_{30}\text{N}_2 = \text{AlON}'$ or ϕ' (McCauley, 1978; Tabary and Servant, 1999b)

AlON region:

- $9\text{Al}_2\text{O}_3:5\text{AlN} - \text{Al}_{23}\text{O}_{27}\text{N}_5 = \text{AlON}$ (McCauley, 1978; Tabary and Servant, 1999a)

AlN polytypoids (Corbin, 1989; Tabary and Servant, 1999a; Tabary *et al.*, 2000):

- $1\text{Al}_2\text{O}_3:4\text{AlN} = 12\text{H}$
- $1\text{Al}_2\text{O}_3:5\text{AlN} = 21\text{R}$
- $1\text{Al}_2\text{O}_3:7\text{AlN} = 27\text{R}$ (Krishnan *et al.*, 1985)
- $1\text{Al}_2\text{O}_3:14\text{AlN} = 32\text{H}$ (Krishnan *et al.*, 1985)

Other polytypoids have also been identified: 8H, 15R, 16H, 33R, 24H, 39R, but the phase equilibria have not yet been clarified. Tabary and Servant (1999a) and Tabary *et al.* (2000) have carried out fairly detailed microstructural characterization of the polytypoids in this system. Figure 2 (McCauley *et al.*, 1988) summarizes selected phase equilibria, bonding, and atomic structure changes in this system. The bonding changes from primarily ionic in $\alpha\text{-Al}_2\text{O}_3$ to covalent in AlN. The electronegativities of aluminum = 1.5, oxygen = 3.5, and nitrogen = 3.0 result in predicted ionic character of $\alpha\text{-Al}_2\text{O}_3$ at 63%, AlN at 43%, and AlON at about 56% (Pauling, 1963). With a magnesium electronegativity of 1.2, MgAl_2O_4 has a predicted ionic character of about 68%. Structurally, the substitution of oxygen into AlN or nitrogen into Al_2O_3 destabilizes the parent structures with the resulting formation of modulated structures. Conceptually, nitrogen substitution into Al_2O_3 causes a local charge imbalance on the substituted nitrogen. This can be reduced by a shift in anion coordination around aluminum from six to four, driving the $\alpha\text{-Al}_2\text{O}_3$ -based phase toward a spinel (MgAl_2O_4) type structure, where the cations are distributed between octahedral and tetrahedral coordination.

This has been confirmed by crystal structure analysis of AlON, first by Goursat *et al.* (1981) and more recently by Tabary and Servant (1999a), confirming the predictive model of McCauley (1978). Basically, in the spinel unit cell, there are 8 aluminum cations in tetrahedral sites, and 15 aluminum and one vacancy in the 16 octahedral sites. The model proposed by McCauley (1978), which assumes a constant number (32) of anions in a spinel unit cell, has been worked out that has successfully been used to describe and account for the unconventional (seemingly nonstoichiometric) composition of both the AlON ($N=5$) and the ϕ' ($N=2$) phases: the model assumes the formula $\text{Al}_{(64+x)/3}\text{Cation Vacancy}_{(8-x)/3}\text{O}_{(32-x)}\text{N}_x$. Table 1 lists the various compositions

Figure 1 Proposed experimental phase-equilibrium diagram for the pseudobinary Al_2O_3 -AlN composition join at one atmosphere of flowing nitrogen (after McCauley and Corbin, 1983).

Figure 2 Crystal chemistry relationships in the Al_2O_3 -AlN system (after McCauley and Corbin, 1983).

predicted by this model from $N=0$ to $N=11$. The 'normal' spinel composition ($N=8$) does not seem to be a stable phase, whereas ALON ($N=5$) and ϕ' ($N=2$) are seemingly stable, stoichiometric phases, verified by many investigators. Yamaguchi and Yanagida (1959) were the first investigators to propose that nitrogen additions to Al_2O_3 would stabilize a spinel-type material. As indicated in Figure 2, AlN has the hexagonal, wurtzite structure, where aluminum is tetrahedrally coordinated with nitrogen. The substitution of oxygen for nitrogen in the wurtzite AlN structure results in structural irregularities (Dorignac *et al.*, 1994) and the

formation of many polytype-like (polytypoid) phases; this is apparently different than SiC which has a vast array of polytypes. However, Ueno *et al.* (1992) and Xia *et al.* (1993) have confirmed that at pressures of about 16–20 GPa, AlN transforms into an octahedrally coordinated rocksalt structure (O_h^5). Augmentation of this analysis of bonding and structure, including MAS-NMR data is given by McCauley *et al.* (2009).

Processing and Microstructures of AlN and AlON

AlN powder can be produced by nitridation of aluminum metal powder or also by the reduction of alumina with admixed fine carbon particles in the presence of nitrogen or ammonia. AlON can be produced by the simple reaction of Al_2O_3 with AlN in nitrogen or by the carbothermal reduction of Al_2O_3 + carbon mixtures (Yawes *et al.*, 1997a; Yawes *et al.*, 1997b; Ish-Shalom, 1982).

Even though AlN is hexagonal, it can be sintered into translucent, almost transparent polycrystalline ceramics (Kuramoto and Taniguchi, 1984; Kuramoto *et al.*, 1989). Coble (1962) demonstrated similar results for α - Al_2O_3 , called Lucalox by the General Electric Company. Both of these materials can never be truly transparent in polycrystalline bodies because of their anisotropic optical properties or birefringence. Note, however, that materials with grain sizes significantly smaller than the wavelength of light could possibly be transparent. AlON, however, being optically isotropic, can be produced in completely transparent ceramic bodies (McCauley and Corbin, 1979). Raytheon Corporation manufactures AlON in sizes up to about $30 \times 30 \times 0.6$ cm for special high-performance applications, including transparent armor and radar windows and domes.

Figure 3 illustrates typical microstructures of AlN (Kuramoto and Taniguchi, 1984; Kuramoto *et al.*, 1989), AlON, and Lucalox. Of course, there are many variations of these microstructures, including grain size, shape, porosity, etc. The microstructure of AlON is hard to resolve optically, because the lack of residual stress at the grain boundaries prevents the polishing treatment from preferentially eroding the boundaries for better contrast. See McCauley *et al.* (1988) for a comprehensive review of microstructures in the Al_2O_3 –AlN system, focusing on the AlON', AlON, and polytypoid regions.

Both pressureless sintering and hot pressing have been used to produce pore-free, fully dense AlN and AlON ceramics. Small amounts of additives (MgO in Al_2O_3 , and CaO and rare earth compounds in AlN) are typically utilized to achieve fully dense, pore-free material. Various chemical-vapor-deposition techniques (e.g., Irene *et al.*, 1975; Silvestri *et al.*, 1975) can be used to produce $Al_xO_yN_z$ films. The effect of oxygen on the sintering and hot pressing of AlN has been studied extensively (Sakai and Iwata, 1977; Sakai *et al.*, 1978). It has been recently shown by Liu *et al.* (2013) that carbothermal reduction can enhance sintering and yield transparent AlON ceramics. Lui *et al.* (2013) also draw attention to other densification aids yielding transparent AlON ceramics. Several investigators have also studied the hot pressing of Al_2O_3 –AlN powder mixtures and determined the resulting properties; however, the formation of the various polytypoids makes the interpretation of their results difficult (Turpin-Launay, *et al.* 1983; Shimpo *et al.*, 1992; Sakai, 1978a,b, 1981a,b); Figure 3(b) is an example of a mixed-phase microstructure.

Sakai (1978a, 1981a,b) has reported on the room- and high-temperature flexural strength of AlN– Al_2O_3 materials in the 0–70 mol% Al_2O_3 region. The final products contained variable amounts of AlN polytypoids. Shimpo *et al.* (1992) investigated the properties of pure AlON as compared to AlON–BN composite materials. In a more comprehensive study, Turpin-Launay *et al.* (1983) and Launay *et al.* (1984) investigated the properties of materials in the AlN– Al_2O_3 system by both reactive hot pressing and reaction sintering; they have referred to these materials as ALUMINALON. Significant variations in hardness, flexure strength, and fracture toughness were observed. The friction, wear resistance, and other mechanical properties of the ALUMINALON family of materials were systematically studied by Trabelsi *et al.* (1987). Since this time, the cubic Al_3O_3N phase has seen commercialization (ALONTM) as impact resistant windows transparent to visible and IR radiation (McCauley *et al.*, 2009).

Properties of AlN and AlON

AlN is a high band gap (about 6.2 eV) dielectric material with a very high thermal conductivity. Slack (1973) estimated the thermal conductivity of a single crystal to be about 320 W m⁻¹ K⁻¹ at 300 K. Since that time, there has been a great deal of effort in

attempting to produce ceramics that approach this value for a variety of high-performance substrate and packaging applications in microelectronics and high-power devices (Ichinose, 1988; Sheppard, 1990). It also has excellent molten-metal corrosion resistance and stability at high temperatures. Extensive high-temperature creep and compressive strength measurements have been carried out on AlN (e.g., Masson *et al.*, 1994). It is also very interesting to note that Heard and Cline (1980) have reported a brittle–ductile transformation in AlN at 0.55 GPa confining pressure; Al₂O₃ does not seem to exhibit this transformation up to a confining pressure of 1.25 GPa. AlON has not been studied in this way yet.

AlON has not been studied as extensively as AlN or α -Al₂O₃. The elastic properties have been worked out by Graham *et al.* (1988), the thermomechanical properties by Quinn *et al.* (1984) and Swab *et al.* (1999), dielectric properties by Westphal and the optical properties by Tropf and Thomas (1991). Kim and Richards (1985) investigated the electrical conductivity of AlON. Neutron irradiation studies are detailed by Jeanne *et al.* (1987). Goursat *et al.* (1976, 1981) have carried out extensive studies on the oxidation of AlON-based materials at high temperature. Table 2 summarizes a variety of representative properties for AlN, AlON, and α -Al₂O₃.

The transparency of AlON to light of various wavelengths makes it suitable as an upconversion material. Thus, if the AlON is densified using erbium and ytterbium as densifying aids, near IR wavelengths can be dissociated into optical wavelengths in both the green and red visible region (Su *et al.*, 2015) due to the double quantum yield associated with Er–Yb interactions. Liu *et al.* (2013) also draw attention to rare earth doped AlON R–G–B emitters using laser excitation as well as rare earth doped AlON being possible materials for the phosphor-converted white LEDs. Thus, AlON appears to have potential use in luminescent materials, as well as in impact resistant windows.

Introduction

Silicon carbide (SiC), also known as carborundum, is an important non-oxide ceramic that exhibits unique properties, such as high temperature strength; resistance to wear, corrosion, and oxidation; tunable thermal and electrical properties; thermal shock resistance; amenable toughness, and a high hardness. Moissanite is an extremely rare mineral of SiC in earth's crust. In industries, it is produced by the Acheson process by reacting high-purity sand with low-sulfur coke at 2200–2500°C via the following reaction:

The high temperature employed in the Acheson process favors the formation of α -SiC (hexagonal crystal structure), a thermodynamically stable, high-temperature phase of SiC. By contrast, the cubic phase, β -SiC, is synthesized by the following vapor phase reactions at 1200–1600°C:

Nano-sized β -SiC powders can be synthesized by pyrolyzing preceramic polymers at 1500°C in an inert atmosphere via the following reaction (Kim *et al.*, 2009):

This chapter summarizes the academic and technological advances in SiC ceramics and discusses their current status in terms of the structure; processing methods; properties including mechanical, electrical, thermal, magnetic, and optical properties; and applications. The processing and properties of SiC-based composites, thin films, and porous ceramics are excluded.

Structure

The fundamental structural unit of SiC is either CSi_4 or SiC_4 , where the central atom (C/S) is bonded to four adjacent atoms (S/C) in a tetrahedral coordination (Izhevskiy *et al.*, 2000). SiC exhibits polymorphism and has more than 250 known polytypes (Cheung, 2006). It is customary to designate all the cubic polytypes as β -SiC, and all the non-cubic structures (hexagonal and rhombohedral) as α -SiC. All the polytypes can be described in a general hexagonal axis system, wherein a particular polytype is described by a SiC bilayer stacking sequence along the c-axis of the hexagonal system. As shown in Fig. 1, the SiC polytypes differ from each other with respect to the stacking sequence of the SiC bilayers. For instance, if the stacking sequence is of the ABCABC... type, then it is referred to as 3C-SiC. Similarly, the stacking sequences of ABCBABC... and ABCACB... are known as 4H and 6H, respectively. Some important properties of the major SiC polytypes are listed in Table 1.

Processing

SiC ceramics can be fabricated by various processing techniques, such as pressureless sintering, gas pressure sintering (GPS), hot pressing, spark plasma sintering (SPS), reaction bonded SiC (RBSC), recrystallization, chemical vapor deposition (CVD), and hot isostatic pressing (HIP). A brief discussion of these processing methodologies is given below.

Pressureless Sintering

SiC is a highly covalently bonded compound. Therefore, it is difficult to densify it without sintering additives. SiC can be sintered via solid-state sintering with the aid of B and C or B_4C and C, which drastically improve its shrinkage kinetics (Prochazka and Popper, 1975). Alternatively, liquid-phase sintering can be performed using metal oxides or mixtures of metal oxides and metal nitride, such as Al_2O_3 and Y_2O_3 (Mulla and Krstic, 1994; Kim *et al.*, 1998) and Al_2O_3 - Y_2O_3 -AlN (Kim *et al.*, 2017a). The oxides react with SiO_2 , which is typically present at the surface of SiC particles, to form an oxide melt and increase the densification. Solid-state sintering of SiC is typically performed at temperatures of approximately 2050–2200°C and results in moderate mechanical properties (flexural strength of 250–450 MPa and fracture toughness of 2.5–4 $\text{MPa m}^{1/2}$). By contrast, liquid-phase sintering of SiC can be achieved at relatively lower temperatures ($\leq 2000^\circ\text{C}$) (Eom *et al.*, 2016; Kim and Kim, 2019). Thus, the interest in liquid-phase-sintered SiC (LPS-SiC) has grown continually owing to its superior mechanical properties relative to those of solid-state-sintered SiC (SSS-SiC) and its cost-effectiveness.

Fig. 1 SiC polytypes: (a) 3C, (b) 4H, and (c) 6H. Modified from Morkoc, H., Strite, S., Gao, G.N., *et al.*, 1994. Large-band-gap SiC, III-V nitride, and II-VI ZnSe-based semiconductor device technologies. *Journal of Applied Physics* 76, 1363–1398.

Table 1 Properties of major SiC polytypes

Polytype	3C	4H	6H
Crystal structure	Zinc blende (cubic)	Wurtzite	Wurtzite
Lattice	Face-centered cubic	Hexagonal	Hexagonal
Symmetry group	F-43m	$P6_3mc$	$P6_3mc$
Lattice constant (Å)	4.35890	3.08100, 10.06100	3.08065, 15.11740
Density (g cm^{-3})	3.216	3.220	3.215
Bandgap (eV)	2.390	3.263	3.023
Bulk modulus (GPa) (300K)	250	220	220

A typical microstructure of an LPS-SiC ceramic with a ternary additive system ($\text{Al}_2\text{O}_3\text{-Y}_2\text{O}_3\text{-CaO}$) is shown in **Fig. 2(a)** (Eom *et al.*, 2016). A unique characteristic of the microstructure of LPS-SiC ceramics is a core/rim structure, formed by grain growth via solution-reprecipitation during sintering. By contrast, the typical microstructure of SSS-SiC shown in **Fig. 2(b)** (Kim *et al.*, 2013b) lacks a core/rim structure, and SSS-SiC ceramics fracture transgranularly.

The factors affecting the densification behavior of SiC ceramics include impurities (C and SiO_2) and the polytype of the SiC powders, sintering atmosphere, and sintering additive composition. The influence of carbon and SiO_2 impurities present in the starting powders on the densification of SiC ceramics is two-fold. In the case of solid-state sintering of SiC ceramics, the presence of a moderate amount of free C is beneficial because it reacts with SiO_2 , removing it from the surface of the SiC particles (Kim *et al.*, 1995c). By contrast, it is detrimental to liquid-phase sintering because of its tendency to react with oxide additives and liberate gaseous products during sintering (Kim *et al.*, 1995c, 1996). The presence of SiO_2 impurity in SiC powders is disadvantageous in solid-state sintering because it liberates gaseous CO by reacting with the free carbon. However, it is beneficial in liquid-phase sintering because it promotes the formation of a liquid phase with other oxide additives and enhances densification (Kim *et al.*, 1996).

The polytype of the starting SiC powders does not have a significant influence on the densification behavior of SiC ceramics; however, it affects the final microstructure following sintering. In LPS-SiC ceramics, the α -SiC starting powders lead to equiaxed grains, whereas β -SiC starting powders lead to elongated grains because of the $\beta \rightarrow \alpha$ transformation of SiC during sintering (Kim *et al.*, 1998; Nader *et al.*, 1999). By contrast, the microstructure of SSS-SiC ceramics is predominantly influenced by the sintering

Fig. 2 Typical microstructures of (a) liquid-phase sintered SiC ceramics and (b) solid state sintered SiC ceramics. Reproduced from (a) Eom, J.H., Seo, Y.K., Kim, Y.W., 2016. Mechanical and thermal properties of pressureless sintered silicon carbide ceramics with alumina-yttria-calcia. *Journal of the American Ceramic Society* 99, 1735–1741. (b) Kim, K.J., Lim, K.Y., Kim, Y.W., 2013b. Control of electrical resistivity in silicon carbide ceramics sintered with aluminum nitride and yttria. *Journal of the American Ceramic Society* 96, 3463–3469.

temperature. When the sintering temperature exceeds a critical temperature, exaggerated grain growth is frequently observed because of $3C \rightarrow 6H$ and/or $6H \rightarrow 4H$ phase transformations of SiC (Williams *et al.*, 1984).

Atmosphere significantly influences the sintering behavior of SiC ceramics. The following effects are reported in SSS-SiC ceramics densified with B and C:

- (1) Argon and vacuum atmospheres are effective in the densification of SiC ceramics via solid-state sintering (Prochazka and Popper, 1975; Ness and Rafaniello, 1994).
- (2) A CO partial pressure of 6.5×10^{-4} MPa does not significantly inhibit densification. However, a CO pressure of 2.5×10^{-3} MPa noticeably inhibits the densification of SiC, and a pressure of 0.1 MPa CO stops the densification of SiC because of the removal of boron present in the sintered body (Prochazka *et al.*, 1979).
- (3) A nitrogen-containing atmosphere retards both the grain growth and densification of SiC ceramics (Prochazka *et al.*, 1979).

The following effects are known in LPS-SiC ceramics with metal oxide additives or metal oxide-AlN mixtures:

- (1) An argon atmosphere is extremely effective in the densification of LPS-SiC ceramics when the liquid phase does not contain nitrogen (Eom *et al.*, 2015).
- (2) A nitrogen atmosphere is more effective than argon when the liquid phase contains nitrogen, e.g., oxynitride or oxycarbonitride liquids that cool to form grain boundary glasses, because a nitrogen atmosphere stabilizes a N-containing liquid phase at high temperatures (Kim and Mitomo, 1999). A nitrogen atmosphere also leads to the growth of N-doped SiC ceramics by dissolution into the liquid phase, resulting in electrically conductive SiC ceramics (Fig. 3; Kim *et al.*, 2015b).
- (3) A vacuum atmosphere is detrimental in the densification of LPS-SiC ceramics because of the accelerated evaporation of the liquid phase during sintering.

The additives in the sintering of LPS-SiC ceramics can be regarded as not only densification aids, but also as key elements for functionality. This is because the electrical, thermal, and mechanical properties are influenced by the composition of the additives as well as the microstructure of the resulting ceramics (Lee *et al.*, 2001a,b; Eom *et al.*, 2015; Jang *et al.*, 2016). Not only for achieving a successful densification of SiC but also for realizing functionality in LPS-SiC ceramics, much effort has been expended to determine new additive compositions because the pressureless sintering of SiC ceramics is preferred for a cost-effective production of the corresponding parts. Thus, various additive systems such as binary, ternary, and quaternary systems have been investigated for a pressureless sintering of SiC ceramics. The additive composition, sintering conditions, and sintered density of pressureless sintered SiC ceramics are listed in Table 2. The relative sintered densities of pressureless sintered SiC ceramics for a binary, ternary, and quaternary additive system are in the ranges 97.0%–99.9%, 96.0%–99.4%, and 96.7%–98.8%, respectively, depending on the additive composition, additive content, and sintering conditions (Table 2). A typical microstructure of a pressureless sintered SiC is shown in Fig. 4(a).

Hot Pressing

SiC ceramics can be densified to near-theoretical densities by hot pressing. During hot pressing, the material transport is accelerated by a plastic flow, and particle rearrangement is performed by the application of a high pressure (10–40 MPa) and diffusion at a high temperature (1700–2000°C). Additionally, the application of pressure helps in reducing the required sintering temperature for densification and inhibits the grain growth. Fig. 4(b) shows a typical microstructure of a monolithic SiC sintered to a high relative density (97.5%) when hot pressed at 1750°C at 20 MPa for 15 min under an Ar atmosphere using fine β -SiC and Al_2O_3 - Y_2O_3 -CaO (sintering additives) as the starting materials (Kim *et al.*, 1995b). However, owing to the uniaxial application of pressure, only simple shapes with anisotropic properties can be sintered by hot pressing. To obtain full densification at low temperatures ($\leq 2000^\circ\text{C}$) and a short holding time (1–6 h), liquid-forming additives such as Al-compounds, RE oxides, and alkaline earth oxides are frequently used (Kim *et al.*, 1997; Lee *et al.*, 2001a,b; Kim *et al.*, 2004; Cho *et al.*, 2018; Malik *et al.*, 2018, 2019). An important advantage of hot pressing

Fig. 3 Schematic illustration of nitrogen-doping mechanism via solution-precipitation in SiC ceramics sintered with $\text{Gd}_2\text{O}_3\text{-Y}_2\text{O}_3$ in a nitrogen atmosphere. Reproduced from Kim, Y.W., Cho, T.Y., Kim, K.J., 2015b. Effect of grain growth on electrical properties of silicon carbide ceramics sintered with gadolinia and yttria. *Journal of the European Ceramic Society* 35, 4137–4142.

Table 2 Sintered density of pressureless sintered LPS-SiC ceramics

Additive system	Sintering additives	Processing conditions	Sintered density (%)	References

over the conventional pressureless sintering is the reduced amount of sintering additives, which improves the high-temperature strength and the thermal and electrical properties.

Gas Pressure Sintering

GPS is used to prevent the decomposition of the nitride additives added for the densification of SiC (Biswas *et al.*, 2001). AlN-containing sintering additives are extensively used for the low-temperature densification of SiC. However, the decomposition of an AlN additive with the evolution of gaseous products is detrimental to the densification of SiC. To avoid this problem, AlN in combination with RE oxides can be used to sinter SiC under a nitrogen pressure (Biswas *et al.*, 2001, 2005). An α -SiC compact containing 10 vol% $\text{AlN-Y}_2\text{O}_3$ as the sintering additives can be completely densified by the GPS at 1950°C under a nitrogen pressure of 10 MPa for 1 h (Biswas *et al.*, 2001). A typical microstructure of a gas-pressure-sintered SiC is shown in Fig. 4(c).

Fig. 4 Typical microstructures of (a) pressureless sintered SiC with $\text{Al}_2\text{O}_3\text{-Y}_2\text{O}_3\text{-Sc}_2\text{O}_3\text{-MgO}$ at 1950°C for 2 h in Ar atmosphere, (b) hot pressed SiC with $\text{Y}_2\text{O}_3\text{-Sc}_2\text{O}_3$ at 1850°C for 2 h in N_2 atmosphere, (c) gas pressure sintered SiC with $\text{AlN-Y}_2\text{O}_3$ at 2050°C for 1 h under 10 MPa of N_2 atmosphere, and (d) spark plasma sintered SiC with $\text{Y}_2\text{O}_3\text{-Sc}_2\text{O}_3$ at 2050°C for 6 h at 60 MPa in N_2 atmosphere. Spark Plasma Sintering

SPS, also known as field-assisted sintering technique (FAST) or pulsed electric current sintering (PECS), is a rapid sintering method that can densify ceramics within a few minutes compared to the several hours taken by hot pressing and pressureless sintering to achieve the same sintered density (Tamari *et al.*, 1995; Barick *et al.*, 2016). The heating in SPS is obtained by the joule heating of the graphite die and powder compact if it is conducting. The internal characteristic of heat generation compared to that of external heating in conventional sintering methods facilitates an extremely high heating or cooling rate of 500 K/min. Such high heating/cooling rates provide a technical advantage of rapid heating of the powder compact to the final sintering temperature while avoiding the loss of grain boundaries. The presence of a high grain boundary area at the sintering temperature facilitates the rapid densification of the powder compact via grain-boundary diffusion. However, the poor thermal conductivity of a ceramic powder compact limits the sample size owing to the thermal shock issues. Regardless, SPS can provide a fully dense ultrafine microstructure, which is difficult to obtain using pressureless sintering and hot pressing. For instance, SiC nanopowders synthesized by mechanical alloying could be successfully densified via SPS to a relative density of 98% with an average particle size of less than 100 nm when sintered at 1700°C for 10 min at a load of 40 MPa in vacuum atmosphere (Yamamoto *et al.*, 2005). A typical microstructure of SPS-SiC is shown in Fig. 4(d).

Reaction-Bonded SiC

Reaction bonding is an economical route to fabricate dense SiC ceramics suitable for use in wear resistance applications and hostile environments (Ness and Page, 1986; Chiang, 1991). RBSC ceramics are prepared by the reactive infiltration of molten Si into a macroporous SiC–C preform. The infiltrated Si reacts with the carbon and generates β -SiC. Thus, the resulting microstructure consists of the initially added α -SiC particles (3–30 μm), in situ synthesized β -SiC, and residual Si. Owing to the low-temperature synthesis ($\sim 1550\text{--}1650^\circ\text{C}$), short time, near net shape fabrication, and no requirement of expensive sintering additives, this fabrication process is highly cost-effective. However, the presence of residual Si (5–15 vol%) in the microstructure renders the RBSC susceptible to corrosion and poor mechanical properties at high temperatures. Fig. 5(a) shows a typical microstructure of an RBSC ceramic infiltrated with molten Si, exhibiting a dense microstructure without the grain growth of SiC.

Fig. 5 Typical microstructures of (a) reaction bonded SiC sintered at 1850°C for 90 min in vacuum, (b) recrystallized SiC sintered at 2400°C for 20 min in argon atmosphere, (c) hot isostatically pressed SiC ceramic processed at 1600°C for 1 h under 350 MPa, and (d) CVD-SiC. Reproduced from (a) Hsu, C.Y., Zhang, Y., Xie, Y., *et al.*, 2019. In-situ measurement of SiC/Si interfacial tensile strength of reaction bonded SiC/Si composite. *Composite Part B* 175, 107116. (b) Guo, W., Xiao, H., Xie, W., *et al.*, 2012. A new design for preparation of high performance recrystallized silicon carbide. *Ceramics International* 38, 2475–2481. (c) Vaßen, R., Stover, D., 2001. Processing and properties of nanophase non-oxide ceramics. *Materials Science and Engineering A* 301, 59–68.

Recrystallized SiC

Recrystallized SiC is a high-temperature structural material with a high purity in the absence of any sintering additives or secondary phases (Kriegesmann, 2004; Guo *et al.*, 2012; Kim *et al.*, 2012c). Such a material is sintered at 2200–2400°C in argon or vacuum by the evaporation–condensation mechanism, and in Ar, it retains its useful mechanical properties up to 2000°C. However, its extensive use is restricted by its residual porosity (~15%) and poor mechanical properties. The porosity and pore structure are amenable via the sintering temperature and initial SiC particle size. Fig. 5(b) shows a typical microstructure of a recrystallized SiC sintered at 2400°C for 20 min in an argon atmosphere.

Other Processing Techniques

HIP is a densification process that involves the simultaneous application of isostatic pressure (200–300 MPa) and temperature (1500–2000°C). HIP ensures: (1) low-temperature (~1500°C) densification of SiC and (2) improved mechanical properties owing to the removal of the residual flaws and porosity by the synergistic effect of the extremely high pressure and temperature. The nano-SiC powder (20 nm) synthesized via laser-assisted pyrolysis can be densified to near-theoretical density without appreciable grain growth when it is hot isostatically pressed at 1500°C for 4 h under an isostatic pressure of 350 MPa (Vaßen *et al.*, 1996). A typical microstructure of hot isostatically pressed SiC is shown in Fig. 5(c).

The CVD method can be used to fabricate high-purity β -SiC monolithic ceramics with a near theoretical density (Gulden, 1969; Drieux *et al.*, 2016). This method facilitates the simultaneous synthesis and densification of in-situ synthesized β -SiC via the pyrolysis of the precursor gases, such as methyltrichlorosilane, at 1200–1800°C. The microstructure exhibits columnar grains of several microns in size. Fig. 5(d) depicts the microstructure of highly dense coarse grained SiC ceramic synthesized via CVD.

Properties

Mechanical Properties

Room-temperature mechanical properties

The mechanical properties of SiC ceramics are governed by their microstructure, fracture energy, flaw size, porosity, and grain boundary chemistry, which in turn depend on the starting composition and processing technique. This section deals with the

Fig. 6 HRTEM micrographs revealing (a) a clean homophase boundary (SiC/SiC) without amorphous intergranular films and (b) a heterophase boundary (SiC/junction phase). Reproduced from Kim, Y.W., Jang, S.H., Nishimura, T., Choi, S.Y., Kim, S.D., 2017c. Microstructure and high-temperature strength of silicon carbide with 2000 ppm yttria. *Journal of the European Ceramic Society* 37, 4449–4455.

capability of different processing techniques for achieving a high fracture energy, reduced flaw size, fine grain microstructure, and high density, which are a prerequisite for achieving excellent mechanical properties. **Table 3** lists room-temperature (RT) flexural strength, fracture toughness, and hardness of SiC ceramics obtained using various processing techniques. The typical ranges of the RT flexural strength, fracture toughness, and hardness of the monolithic SiC ceramics are 321–950 MPa, 2.9–7.5 MPa m^{1/2}, and 20.0–29.3 GPa, respectively.

High-temperature strength

LPS-SiC ceramics possess excellent mechanical properties at RT and can be processed at temperatures below those for SSS-SiC. However, the high-temperature strength of LPS-SiC is often limited by the softening of the intergranular films (Kim *et al.*, 2005; Seo *et al.*, 2016a,b). Therefore, continued studies were directed toward developing high-refractory intergranular films with various combinations of sintering additives (Kim *et al.*, 2007; Lim *et al.*, 2013). **Table 4** summarizes the high-temperature flexural strengths of hot-pressed SiC and CVD-SiC. As is evident from the table, a few AlN-RE (RE=Sc, Lu) oxide systems exhibit RT strength retention up to 1600°C. A SiC ceramic sintered at 2200°C with 2000 ppm yttria showed an extremely high strength of 981 MPa at 2000°C, which was 74% higher than its RT strength. This excellent strength at 2000°C was attributed to the strengthening effect of the plastic deformation and clean boundaries (Fig. 6; Kim *et al.*, 2017c). A CVD-SiC showed an excellent strength of 869 MPa at 1400°C, which is 91% of its RT strength. This excellent strength is attributed to the absence of amorphous intergranular films. In summary, monolithic SiC with a coarse microstructure in the absence of impurities and amorphous films at the grain boundary will show high strength retention at elevated temperatures.

Electrical Properties

SiC is an electrical semiconductor with a wide bandgap. The electrical resistivity of monocrystalline SiC at RT ranges from 5.3×10^{-3} to 3×10^{11} Ω cm, depending on the dopant type and concentration (Table 5). In contrast, the RT electrical resistivity of polycrystalline SiC ceramics ranges between 3.5×10^{-3} and 3×10^{13} Ω cm depending on the additive composition and microstructure (Table 6). The critical factors affecting the electrical conductivity of LPS-SiC ceramics include the SiC polytype, grain boundary structure, soluble atoms, porosity, and grain size (Kim *et al.*, 2019d).

Until now, over 250 SiC polytypes have been reported (Ramsdell, 1945; Cheung, 2006). Each SiC polytype exhibits different electrical properties owing to differences in the stacking sequence and bandgap. Among them, 3C-SiC (β -SiC) and 6H-SiC (α -SiC) powders are the most widely available polytypes at present. Generally, the LPS-SiC ceramics processed from β -SiC powder show a lower electrical resistivity (3.5×10^{-3} – 3.4Ω cm) (Zhan *et al.*, 2001; Kim *et al.*, 2011, 2015b) than those processed from α -SiC (5.4 – $1.2 \times 10^{13} \Omega$ cm) (Koumoto *et al.*, 1987; Cho *et al.*, 2016; Kim *et al.*, 2017a). Specifically, the electrical resistivity values of the LPS-SiC ceramics sintered with AlN- Y_2O_3 - Sc_2O_3 are $6.7 \times 10^{-1} \Omega$ cm and 5.4Ω cm when β -SiC and α -SiC are used as the starting powders, respectively (Cho *et al.*, 2016). In most cases, although the $\beta \rightarrow \alpha$ phase transformation of SiC partially occurs during sintering (Cho *et al.*, 2016; Jang *et al.*, 2016), the β -SiC starting powder typically leads to a lower electrical resistivity than that of the α -SiC powder under the same sintering conditions. This is because of the smaller bandgap of 3C-SiC (2.4 eV) and lower ionization energy of the nitrogen donors in 3C-SiC (~ 60 meV) compared to those in 6H-SiC (3.0 eV and 100–155 meV) (Ikeda *et al.*, 1980; Iwata *et al.*, 2003).

The electrical resistivity of the LPS-SiC ceramics is affected by the grain boundary structure. LPS-SiC ceramics with clean SiC/SiC grain boundaries exhibit lower electrical resistivities than those with amorphous intergranular films at the SiC/SiC boundaries. Specifically, polycrystalline SiC ceramics, containing amorphous grain boundary films at the SiC/SiC boundaries, have electrical resistivities of the order of 10^{10} – $10^{13} \Omega$ cm at RT (Kim *et al.*, 2014a; Liang *et al.*, 2015; Kim *et al.*, 2017a). By contrast, polycrystalline SiC ceramics, which possess clean SiC/SiC boundaries (i.e., no amorphous films), show significantly low electrical resistivities of the order of 10^{-2} – $10^0 \Omega$ cm at RT (Kim *et al.*, 2012c; Lim *et al.*, 2013; Kim *et al.*, 2017c).

Dopants act as acceptors or donors in the SiC lattice. The ability to dope the SiC lattice is limited by the solid solubility limit. The soluble atoms in the SiC lattice include Al, B, Ga, Sc, N, P, Be, O, and V (Ikeda *et al.*, 1980; Tajima and Kingery, 1982; Takeda *et al.*, 1987; Persson *et al.*, 1999; Wirth *et al.*, 1999; Laube *et al.*, 2002; Tamulaitis *et al.*, 2004; Heera *et al.*, 2006; Racka *et al.*, 2015). Al, B, Ga, and Sc act as p-type dopants, whereas N and P act as n-type dopants in the SiC lattice (Kim *et al.*, 2019d). However, Be, O, and V tend to create deep levels within the bandgap, which can capture carriers, leading to a semi-insulating or insulating SiC (Takeda *et al.*, 1987; Ventra and Pantelides, 2000; Tamulaitis *et al.*, 2004). Because the sintering additives and sintering atmosphere often contain n- or p-type dopants, e.g., Al_2O_3 , AlN, B, B_4C , and Sc_2O_3 as

additives and nitrogen as the sintering atmosphere, the dopant atoms are incorporated into the SiC lattice during the grain growth via a solution-reprecipitation mechanism. Typical examples are N-doping of the SiC grains during the sintering of SiC ceramics with $\text{Y}_2\text{O}_3\text{--Gd}_2\text{O}_3$ additives in a nitrogen atmosphere (Fig. 3) (Kim *et al.*, 2015b) and Al doping during the sintering of SiC ceramics with $\text{AlN--Y}_2\text{O}_3$ additives in a nitrogen atmosphere (Kim *et al.*, 2013b). Thus, the careful selection of the sintering additive composition and sintering atmosphere is important for achieving the desired electrical resistivity in LPS-SiC ceramics.

Porous LPS-SiC ceramics show a substantially higher electrical resistivity than the dense LPS-SiC ceramics (Zhan *et al.*, 2001; Ihle *et al.*, 2006). For example, the electrical resistivity of the SiC ceramics increased from 0.10 to 1.41 $\Omega\text{ cm}$ with increasing porosity from 38.8% to 42.2% when SiC was sintered with $\text{Al}_2\text{O}_3\text{--Y}_2\text{O}_3$ additives (Ihle *et al.*, 2006).

The LPS-SiC ceramics exhibited a tendency of increasing resistivity with decreasing grain size because of the grain boundary scattering of the carriers. Specifically, a LPS-SiC ceramic with an average grain size of 3.5 μm showed a higher electrical resistivity ($5.2 \times 10^{-2} \Omega\text{ cm}$) than that with an average grain size of 5.5 μm ($8.9 \times 10^{-3} \Omega\text{ cm}$) at RT (Kim *et al.*, 2015b). However, a deviation from the above trend was also observed when the $\beta \rightarrow \alpha$ phase transformation of SiC occurred simultaneously with the grain growth in LPS-SiC ceramics (Kim *et al.*, 2019d).

Thermal Properties

As a covalently-bonded compound, SiC transports heat primarily via phonons at RT (Kim *et al.*, 2014b). The intrinsic thermal conductivities of 6H and 4H (N-doped) single crystals are reported as 490 W(m K)^{-1} and 342 W(m K)^{-1} at RT, respectively (Slack, 1964; Wei *et al.*, 2013). However, the thermal conductivity values of polycrystalline SiC ceramics are much lower than the intrinsic values because of the defects in the SiC grains and grain boundaries. There is a wide variation in the reported thermal conductivity data of polycrystalline SiC ceramics (32–262 W(m K)^{-1}), depending on the composition and quantity of the sintering additives (Table 7). The most detrimental element is Al because Al creates additional silicon vacancies in the SiC lattice according to the following defect equation: $\text{Al}_2\text{O}_3 \rightarrow 2\text{Al}_{\text{Si}} + 3\text{O}_{\text{C}} + \text{V}_{\text{Si}}^{\bullet\bullet}$ (Zhou *et al.*, 2003; Kim and Kim, 2019). These vacancies cause phonon scattering and reduce the thermal conductivity. Thus, a LPS-SiC with Al-containing additives revealed a conductivity of 32–83 W(m K)^{-1} (Zhan *et al.*, 2002; Sigl, 2003; Zhou *et al.*, 2003; Eom *et al.*, 2016; Seo *et al.*, 2018; Kim *et al.*, 2019a), whereas the LPS-SiC ceramics sintered with $\text{Y}_2\text{O}_3\text{--RE}_2\text{O}_3$ (RE = Sc, Lu, Gd, Sm, La) exhibited a conductivity of 181–262 W(m K)^{-1} (Zhou *et al.*, 2003; Kim *et al.*, 2014b; Jang *et al.*, 2016; Cho and Kim, 2017; Seo *et al.*, 2017). Another critical impurity in the SiC lattice is oxygen because oxygen generates additional silicon vacancies therein according to the following defect equation: $\text{SiO}_2 \rightarrow \text{Si}_{\text{Si}} + 2\text{O}_{\text{C}} + \text{V}_{\text{Si}}^{\bullet\bullet}$ (Cho and Kim, 2017). As shown in Fig. 7, the thermal conductivity increases with decreasing lattice oxygen content in LPS-SiC ceramics without Al-containing additives. The data in the circle were reported from those of the LPS-SiC ceramics sintered with Al-containing additives. It is clear that the addition of Al-containing additives leads to much lower thermal conductivities than those with additive compositions without Al compounds by the increased phonon scattering at Si vacancies. The thermal conductivity of the SiC ceramics sintered with Al-containing additives was insensitive to the lattice oxygen content. These results confirm that Al incorporation in the SiC lattice is more detrimental to oxygen incorporation for improving the thermal conductivity of the LPS-SiC ceramics.

Table 7 Thermal conductivity of polycrystalline SiC ceramics

Sintering additives	Processing conditions	Thermal conductivity (RT) ($\text{Wm}^{-1}\text{K}^{-1}$)	References

Fig. 7 Effect of the lattice oxygen content on the thermal conductivity of LPS-SiC ceramics. Literature data were also plotted for comparison. Reproduced from Cho, T.Y., Kim, Y.W., 2017. Effect of grain growth on the thermal conductivity of liquid-phase sintered silicon carbide ceramics. *Journal of the European Ceramic Society* 37, 3475–3481.

The thermal conductivity of SSS-SiC depends on the amount of boron and carbon additives and microstructure. By optimizing these, a thermal conductivity of $192 \text{ Wm}^{-1} \text{ K}^{-1}$ was obtained in SSS-SiC ceramics sintered with 0.4 wt% boron and 0.4 wt% carbon (Li *et al.*, 2014).

Other Properties

Concerning optical properties, β -SiC has important applications such as in domes and windows in armor, hypersonic missiles, and thermal control for thin-disc lasers. Transparent β -SiC was successfully fabricated by the pyrolysis of methyltrichlorosilane in a hot-wall, low-pressure CVD reactor exhibiting excellent transmittance ($\sim 60\%$) in the wavelength range of $0.5\text{--}6 \mu\text{m}$ (Goela *et al.*, 1993). Optical transparency in pure cubic SiC (99.9997%) was attributed to the columnar grains grown parallel to the $\langle 111 \rangle$ direction, absence of twins, stacking faults, and low densities of dislocations (Kim *et al.*, 1995a).

SiC-based magnetic semiconductors are potential materials for high-temperature and high-frequency magnetic devices owing to their high thermal stability and high thermal conductivity. Liu and Wang (2018) synthesized tunable SiC powders via microwave heating, which exhibited a high saturated magnetization (M_s , 0.9 emu/g, 300K) attributed to the existence of point defects in the SiC lattice and interface between the SiC and SiO_x . Furthermore, dilute magnetic semiconductors (DMS) are promising candidates for spintronics where transition metals such as Sc, Ti, V, Cr, Mn, Fe, Co, and Ni with partially filled d states can be doped for transforming spin-frustrated semiconductors (like SiC) to a ferromagnetic phase. Vanadium-doped SiC nanowires fabricated via CVD exhibited a mixture of the diamagnetic phase (VC and non-doped β -SiC) and ferromagnetic or paramagnetic phase (V-doped SiC) owing to the low solubility of V in SiC (Seong *et al.*, 2009). Fe-doped bulk SiC fabricated by hot-pressing exhibited ferromagnetic hysteresis at RT (Kim and Kim, 2012).

Applications

The important applications of SiC can be broadly divided into two categories: structural and functional applications. The structural applications include abrasives, car disc brakes, car clutches, armor plates in bulletproof vests, kiln furniture, sand blasting nozzles, automotive water pump seals, bearings, mechanical seals, and extrusion dies. In the manufacturing industry, SiC is widely used in machining processes such as grinding, honing, water-jet cutting and sandblasting. Cutting tools made of SiC whisker-reinforced alumina are commercially available in the market. In the automobile industry, carbon-reinforced SiC disc brakes are used in high-performance cars owing to their lower weight, high temperature stability, and high thermal conductivity. In the semiconductor industry, various SiC parts such as focus rings, wafer boats, tubes, susceptors, and dummy wafers are widely used for semiconductor processing. In the astronomy industry, SiC mirrors are much desirable owing to their low thermal expansion coefficient, high hardness, rigidity, and thermal conductivity. In foundries, SiC crucibles are used to hold molten metals (Peter *et al.*, 2011). Porous SiC ceramics are used as diesel particulate filters (O'Sullivan *et al.*, 2004), molten metal filters, membranes for water purification (Kim *et al.*, 2017b) and gas separation, and hot-gas filters. In steel production, SiC is used as a fuel to increase the tap temperature and adjust the Si and C content. In the nuclear industry, SiC is being developed as a matrix material for tristructural isotropic (TRISO) fuel particles to provide multiple barriers to fission products, conduct heat, high temperature stability, radiation damage resistance, and oxidation resistance against high-temperature steam (Kim *et al.*, 2019a). SiC fiber is

used as a reinforcement for SiC matrix composites, which are used as turbine components, such as turbine shrouds, combustors, nozzles, and combustor liners (Steibel, 2019).

The functional applications of SiC include varistors, light-emitting diodes (LEDs), and semiconductor devices. SiC-semiconductor-based power devices such as JFETs and MOSFETs are already commercialized exhibiting advantages like a fast response, high temperature, and high-voltage applications. SiC is an important LED component that is used as a substrate for growing GaN devices and a heat spreader in high-power LEDs (Stringfellow, 1998). SiC fibers ($\sim 15 \mu\text{m}$) are widely used in thin-film pyrometry to measure high flame temperatures in the range of 800–2500K (Maun *et al.*, 2007). SiC-based heating elements are widely used in the melting of glass, non-ferrous metals, and heat treatment of metals (Deshmukh, 2005).

Summary

SiC is an important ceramic material that is widely used in automotive, steel, electronic, astronomy, semiconductor, and nuclear industries owing to its unique set of properties such as high temperature strength, resistance to wear and corrosion, tunable thermal and electrical properties, thermal shock resistance, amenable toughness, and high hardness. Structurally SiC exhibits more than 250 polymorphs, among which all the cubic polytypes are referred to as β -SiC, and all the non-cubic structures (hexagonal and rhombohedral) are known as α -SiC. Hexagonal SiC is synthesized via the Acheson process, whereas cubic SiC is synthesized via vapor-phase reactions and the pyrolysis of polymeric precursors.

Owing to the high covalent bonding nature and low self-diffusivity, SiC is difficult to densify without sintering additives. B- and C-additives are used for solid-state sintering at 2050–2200°C, whereas liquid-phase sintering, facilitated by the use of various lower-temperature liquid-forming additives (oxides and nitrides), can be achieved at $\leq 2000^\circ\text{C}$. Contrary to pressureless sintering, hot pressing requires less additives for densification, thus facilitating improved high-temperature strengths and thermal and electrical properties. Spark plasma sintering can be employed to develop fully dense ultrafine microstructures, providing improved strength and hardness. Gas pressure sintering is advantageous for nitride additive systems because it prevents the decomposition of nitride additives at high temperatures by applying a nitrogen overpressure ($\sim 10 \text{ MPa}$). Reaction-bonded SiC offers an economical route to fabricate dense SiC ceramics that exhibit attractive mechanical properties at RT; however, their maximum application temperature is restricted by the presence of residual Si, which melts at 1414°C. Recrystallized SiC is widely used for making kiln furniture because it can retain its useful mechanical properties up to 2000°C in an inert atmosphere. CVD and HIP are expensive methods to fabricate high-purity and highly dense SiC ceramics suitable for high-temperature and functional applications sensitive to the impurity concentration.

The typical flexural strength, fracture toughness, and hardness of SiC ceramics at RT are 321–950 MPa, 2.9–7.5 MPa $\text{m}^{1/2}$, and 20.0–29.3 GPa, respectively. The best high temperature strength reported in LPS-SiC lies in the range of 500–600 MPa at $\sim 1600^\circ\text{C}$. The electrical resistivity at RT of monocrystalline and polycrystalline SiC lie in the ranges 5.3×10^{-3} – $3 \times 10^{11} \Omega \text{ cm}$ and 3.5×10^{-3} – $3 \times 10^{13} \Omega \text{ cm}$, respectively, depending on the dopant type and concentration in the monocrystalline SiC and additive composition and microstructure in the polycrystalline SiC. Depending on the composition and quantity of the sintering additives, the reported thermal conductivity data of the polycrystalline SiC ceramics varies from 32 to 262 $\text{W}(\text{m K})^{-1}$ at RT. SiC ceramics also exhibit attractive optical properties that have applications such as domes and windows in armor, hypersonic missiles, and thermal control for thin disc lasers. SiC-based magnetic semiconductors are established as potential materials for high-temperature and high-frequency magnetic devices owing to their high thermal stability and high thermal conductivity.

High Thermal Conductivity Ceramics

Mikito Kitayama, Fukuoka Institute of Technology, Fukuoka, Japan

Introduction

High thermal conductivity ceramics have drawn much attention due to energy and environment-related issues after the beginning of the 21st century. In order to reduce the emission of carbon dioxide, energy sources need to shift from fossil fuel to renewable energy sources like solar, wind and hydrogen power generations, in which so-called power modules are necessarily used to convert and control electric power. Power electronic devices are key technologies for this purpose, and also, they will be widely used for electric vehicles in the near future according to the world-wide trend for the replacement of fossil fuels towards electric power. Thermal dissipation has been always one of the critical issues for semiconductor devices, since they must be cooled to avoid thermal runaway and resultant failure of devices. Thus, ceramic substrates have been utilized for high-power electronic devices such as switching devices, oscillating devices, semiconductor lasers and LED lighting. Large thermal stresses induced by large electrical power has been posing great challenges for the assembly of the devices (Yamagiwa, 2010), especially for brittle ceramic substrates that provide functions of electrical insulation and heat dissipation.

High thermal conductivity ceramics are also used for heat exchangers, which are widely used in highly efficient modern power plants with cogeneration systems, combustion furnaces, chemical and petrochemical plants. The world-wide trends for energy saving should accelerate the use of ceramic heat exchangers for these applications, in which the materials must have durability at high temperature, in corrosive environments and under high thermal stress as well as high thermal conductivity.

Table 1 summarizes selected properties of commercial engineering ceramics. For more than half a century, aluminum oxide (Al_2O_3) has been an ideal ceramic material for semiconductor packaging and substrates for electronic circuits with excellent electrical properties and relatively low production cost. In the 1980s, strong demands mentioned above pushed the development of high thermal conductivity aluminum nitride (AlN) that was reported to have high intrinsic thermal conductivity (Slack, 1973, 1987) about 10 times higher than Al_2O_3 . In the 21st century, the demand for more efficient control of electric power and the advancement toward higher voltage, larger current, greater power density, is poised to be accelerated with the replacement of silicon by the wide-band gap semiconductors (silicon carbide and gallium nitride), which are able to operate at much higher temperatures than silicon. However, the thermal expansion coefficient differential between wiring materials, such as Cu, and AlN substrate yield large thermal stresses that cause cracks after thermal cycle tests due to the poor mechanical properties of AlN ceramics (Yamagiwa, 2010), and this also makes the machining process for through-holes difficult. Moreover, large dielectric dispersion around ~ 1 GHz (Nakayama *et al.*, 1996) and degradation of electric resistance at temperatures greater than 200°C (Naba, 2012) were reported for AlN ceramics, which accelerated the development of high thermal conductivity silicon nitride (Si_3N_4) ceramics that inherently possess excellent mechanical properties, much better than AlN, due to the interlocking of rod-like β - Si_3N_4 crystals within the microstructure (Becher, 1991) and intrinsic thermal conductivity as high as AlN (Haggerty and Lightfoot, 1995). Although silicon carbide (SiC) ceramics were known to have even higher intrinsic thermal conductivity than AlN (Slack, 1973), its electrical properties are basically those of a semiconductor, which would make its application as electrical circuit substrates very difficult; however, its excellent thermal and chemical stability as well as low thermal expansion coefficient make it a suitable material for heat exchangers.

Fig. 1 demonstrates how the thermal conductivities of AlN and SiC ceramics have advanced during the past 50 years after the prediction of their high intrinsic values by Slack in 1973 and that of Si_3N_4 by Haggerty and Lightfoot (1995). In this chapter, the intrinsic thermal conductivities of high thermal conductivity materials are first reviewed. Then, technological advancements for improving the thermal conductivities of AlN, SiC and Si_3N_4 ceramics will be separately reviewed in detail, followed by a short summary. High thermal conductivity ceramics were reviewed by Watari (2001) and therefore this we mainly focuses on the advancements in the 21st century.

Table 1 Properties of engineering ceramics^a

Materials	Density (gcm^{-3})	Bending strength (MPa)	Fracture toughness ($\text{MPa}\sqrt{\text{m}}$)	Thermal expansion coefficient (10^{-6} K^{-1})	Thermal conductivity ($\text{W m}^{-1} \text{ K}^{-1}$)	Dielectric strength (kV mm^{-1})	Resistivity (Ωm)	Relative permittivity
SiC	3.1	450–540	2–5	3.7	60–200	–	10^5 – 10^8	9–10
AlN	3.3	220–310	3–3.5	4.6	67–150	14–16	$> 10^{12}$	6–8.5
Si_3N_4	3.2	600–750	6.5–7.5	2.7–3.4	27–54	12–18	$> 10^{12}$	7–9
Al_2O_3	3.9	300–400	3.5–4	7–8	18–24	10–18	$> 10^{12}$	9–10
ZrO_2	6.0	750–1000	4–8	10–11	3	11–13	10^{11} – 10^{12}	28–33
SiO_2	2.2	67–69	–	0.51–0.58	1.38	25–40	10^{14}	3.7–8

Opportunities for enhancing the thermal conductivity of SiC and Si_3N_4 ceramics through improved processing. *Ceramic Engineering & Science Proceedings* 16, 475–487.

Intrinsic Thermal Conductivities

Silver has the highest thermal conductivity of any metal at room temperature where its thermal conductivity, κ , is $427 \text{ W m}^{-1} \text{ K}^{-1}$. For copper, the value is $398 \text{ W m}^{-1} \text{ K}^{-1}$. In metals, the heat is carried primarily by electrons, while in non-metals it is carried primarily by phonons, the quantum mechanical description of a lattice vibration. For example, diamond exhibits κ value as high as $2000 \text{ W m}^{-1} \text{ K}^{-1}$ exceeding those of silver and copper. Those crystals for which κ at room temperature exceeds $100 \text{ W m}^{-1} \text{ K}^{-1}$ were considered to possess high thermal conductivity, and those of simple adamantane (diamond-like) compounds were investigated (Slack, 1973).

As an example for the effects of temperature on the thermal conductivity, that of a large, high-purity CVD-SiC single crystal (Slack, 1964) is shown in Fig. 2 (Haggerty and Lightfoot, 1995) along with its estimated intrinsic behavior (Kingery *et al.*, 1976). From 0K, the thermal conductivity increases rapidly with temperature, reaches a maximum value at approximately 55, then decreases with increasing temperature. For temperatures less than several hundred degrees Celsius, heat transfer is dominated by phonon transport and thermal conductivity (κ) is given by:

$$\kappa = \frac{1}{3} C_v v \lambda_{\text{effective}} \quad (1)$$

where C_v is the heat capacity of a unit volume, v is the phonon velocity, and $\lambda_{\text{effective}}$ is the effective phonon mean free path (Kingery *et al.*, 1976). The overall effect of temperature on κ is defined by the temperature dependencies of the individual terms. Fig. 2 also shows the effect of temperature on the intrinsic mean free path, which was analyzed for the high and low temperature domains that are defined in terms of the Debye temperature, θ_D . Between the temperature corresponding to the maximum conductivity and $T = 1/6 \cdot \theta_D$, the low temperature mean free path decreases exponentially with temperature, making κ proportional to $\exp(\text{constant} \cdot \theta_D \cdot T^{-1})$. At high temperature, $T \geq \theta_D$, the Peierls' adaptation of the Debye model predicts that:

$$\kappa = B \bar{M} \delta \theta_D^3 T^{-1} \gamma^{-2} \quad (2)$$

where B = some constant, $\bar{M}$ = average mass of an atom in the crystal, δ^3 = average volume occupied by one atom of the crystal (volume of a unit cell divided by n , the number of atoms in a primitive cell), and γ = Grüneisen's constant (Slack, 1973). This derivation gives the experimentally observed T^{-1} dependence. Between these two regimes, the conductivities of intrinsic materials generally change progressively between these limiting behaviors.

Fig. 2 Thermal conductivity data for a high purity α -SiC single crystal (solid line) as well as the projected intrinsic behavior (dashed line). Also shown are thermal mean free paths in SiC defined by intrinsic thermal effects. Adapted from Slack, G.A., 1964. Thermal conductivity of pure and impure silicon, silicon carbide, and diamond. *Journal of Applied Physics* 35, 3460–3466. Source: $\bar{M}$ = average mass of an atom in the crystal, δ^3 = average volume occupied by one atom of the crystal (volume of a unit cell divided by n , the number of atoms in a primitive cell), and γ = Grüneisen's constant.

Table 2 summarizes the parameters affecting κ , κ_{int} : intrinsic κ at room temperature calculated according to Eq. (2), and κ_{exp} : the highest κ at room temperature experimentally determined, of adamantane compounds and selected ceramic materials with high κ . These parameters imply four conditions of high κ materials as follows:

- (1) Low atomic mass,
- (2) Strong interatomic bonding,
- (3) Simple crystal structure, and
- (4) Low anharmonicity.

Conditions (1) and (2) mean high θ_D , condition (3) means low n , and condition (4) means small γ . Thus, simple adamantane crystals composed of elements with low atomic mass are the representative high κ materials as shown in **Table 2**. One exception in this table would be Si₃N₄ with $n = 28$. As is true of Y₂O₃, which exhibits an anomalously high conductivity, it appears that the primitive cell of Si₃N₄ should be approximated as an ensemble of smaller cells having different spatial orientations. For Si₃N₄, possible effective values of n are 14 and 7, which yield κ_{int} at room temperature, ~ 200 and ~ 320 W m⁻¹ K⁻¹, respectively (Haggerty and Lightfoot, 1995).

Imperfections in the crystal lattice resulting from impurity atoms, interstitials, vacancies, dislocations, twins, crystallographic disorder, etc., all increase anharmonicity in the vibrational modes (Touloukian *et al.*, 1970). As with intrinsic thermal effects, the

Fig. 3 Normalized low temperature thermal conductivities as a function of porosity for randomly distributed, uniform diameter, spherical pores (upper curve), and square ordered arrays of cylindrical pores whose axes are perpendicular to the direction of heat flow (pore lengths = 25%, 50% and 100% of sample length).

anharmonicities reduce the thermal conductivity by reducing the effective phonon mean free path. The effect of defects on the effective mean free path is given by:

$$\frac{1}{\lambda_{\text{effective}}} = \frac{1}{\lambda_{\text{thermal}}} + \frac{1}{\lambda_{\text{impurity}}} + \frac{1}{\lambda_{\text{defect}}} + \text{etc.} \quad (3)$$

where λ_{thermal} is the thermal mean free path, $\lambda_{\text{impurity}}$ is the mean free path defined by impurities, and λ_{defect} is the mean free path defined by defects other than impurities. In a crystalline lattice, the value of $\lambda_{\text{impurity}}$ is approximated by the distance between impurity atoms $\sim (\text{number per volume})^{-1/3}$. For example, 1 vol% solute impurity atoms are spaced $\sim 10 \text{ \AA}$ for SiC, which is smaller than the thermal mean free path for temperatures below 1600K as shown in Fig. 2 (Haggerty and Lightfoot, 1995). As summarized in Table 2, significant discrepancies in κ_{int} and κ_{exp} are confirmed, which are mainly due to the existence of impurities in these crystals. It was pointed out that the dominant impurity was oxygen in AlN (Slack, 1973) as was true in Si_3N_4 (Kitayama *et al.*, 1999c), which will be discussed in detail as well as the other impurity effects on thermal conductivity in SiC later below.

The effects of pores on the thermal conductivity of solids are extraordinarily complex in detail, however two models (Russell, 1935; Loeb, 1954) adequately describe the effects of uniform pores on the thermal conductivity of dielectric materials containing up to 60% porosity. The Russell model treats only spherical pores; however, it includes both radiation and the conductivity of the gas phase which can become significant in materials having open pore structures when used at high gas pressures. The Loeb model treats both spherical and cylindrical pores having arbitrary aspect ratios. However, in Loeb's model, heat transport across pores is assumed to occur only by radiation. Despite fundamental differences, both models predict values that agree closely with measured values for temperatures up to 900°C in dielectrics having porosity levels up to 60% (Francl and Kingery, 1954). In agreement with experimental observations, the calculated conductivity shown in Fig. 3 (Haggerty and Lightfoot, 1995) decreases proportionally with increasing concentration of spherical pores.

Silicon Carbide

Since it is very difficult to obtain dense SiC ceramics due to its strong covalent bonding, the use of applied pressure during sintering and the addition of effective sintering additives were the keys to obtain dense ceramics. Initial research on SiC ceramics employed hot-pressing (HP) for fabricating dense SiC ceramics. An extensive study of different sintering aids suggested that Al (either in elemental form or as an oxide) would result in a high density ($> 98\%$ of theoretical) material (Alliegro *et al.*, 1956), and the densification behaviors using Al_2O_3 as a sintering additive were studied in detail by Lange (1975). The pressureless sintering (PLS) of sub-micron SiC powder using B and C as sintering additives successfully fabricated dense SiC ceramics at more than 2100°C (Prochazka, 1974). Liquid-phase sintering using Al_2O_3 and Y_2O_3 as sintering additives lowered the HP temperature to 2000°C for obtaining dense SiC ceramics (Cutler and Jackson, 1988). Finally, the PLS of high purity B-doped sub-micron SiC powder successfully fabricated dense SiC ceramics at 2000°C using BeO as a sintering additive (Yasutomi *et al.*, 1995).

Table 3 chronologically arranges the development of high thermal conductivity SiC ceramics including sintering aids, sintering methods and conditions and resultant κ values reported, which demonstrates that the type of sintering additives remarkably affects the κ values of dense SiC. The highest κ of about $270 \text{ W m}^{-1} \text{ K}^{-1}$ was obtained when BeO was employed (Takeda *et al.*, 1986); however much lower κ values were reported for other sintering additives: $170 \text{ W m}^{-1} \text{ K}^{-1}$ for B addition (Takeda *et al.*, 1986), $60 \text{ W m}^{-1} \text{ K}^{-1}$ for Al addition (Takeda *et al.*, 1986), $120\text{--}235 \text{ W m}^{-1} \text{ K}^{-1}$ for Al₂O₃ addition (Kinoshita and Munekawa, 1997) and $75\text{--}90 \text{ W m}^{-1} \text{ K}^{-1}$ for Al₂O₃-Y₂O₃ addition (Liu and Lin, 1996). These differences were reasonably explained by the solid solubilities of these elements in the SiC crystal lattice (Takeda, 1988). The solid solubility of Be was reported to be $\sim 8 \times 10^{18} \text{ cm}^{-3}$, which was much less than those of B and Al: 1×10^{20} and $1 \times 10^{21} \text{ cm}^{-3}$, respectively (Vodakov and Mokhov, 1973). Therefore, it can be concluded that the κ enhancement of SiC ceramics, as shown in Fig. 1, is primarily attributed to the optimization of sintering additives. However, it should be noted that the resistivities of SiC ceramics sintered with B and C were as low as of the order of $10^2 \Omega \cdot \text{m}$. Although the addition of BeO increases the resistivities to the order of $10^{10} \Omega \cdot \text{m}$, the electrical properties of these SiC ceramics were found to show the typical behavior of a varistor (Takeda, 1988).

The effect of phase development of SiC polytypes on the conductivity of ceramics should be noted. Works by Sakai and Aikawa (1988) and Liu and Lin (1996) reported that the conductivity of SiC decreases appreciably with increasing fraction of 4H SiC. However, a detailed relationship between the conductivity of SiC ceramics and phase content of 4H, 8H, 15R, etc., has not yet been clarified. The polytype 3C SiC, which has a cubic structure, is postulated to have the highest thermal conductivity among the SiC polytypes because of its highly symmetric crystal structure. SiC ceramics consisting of a large amount of 3C were fabricated by pressureless sintering of B-doped 3C-SiC powders with BeO addition (Yasutomi *et al.*, 1995) and this material was reported to have a κ value of $230 \text{ W m}^{-1} \text{ K}^{-1}$. Since the relative density of this material was 94%, further enhancement of the conductivity would be expected on full densification.

Aluminum Nitride

As well as SiC, initial research employed hot-pressing (HP) for fabricating dense AlN ceramics. The lattice oxygen was already found to be the main impurity that decreased the thermal conductivity of AlN ceramics (Slack, 1973; Sakai *et al.*, 1978), and the maximum solid solubility of oxygen in AlN at about 2000°C has been reported to be $2 \times 10^{21} \text{ cm}^{-3}$ (1.6 wt%) (Slack, 1973). Extensive studies of different sintering aids suggested that alkaline-earth oxides and rare-earth oxides were effective sintering additives for pressureless sintering (PLS) of AlN (Komeya *et al.*, 1981, 1982). These sintering additives form the liquid phase by the eutectic reactions between AlN, sintering additives and Al₂O₃ that normally presents as a surface film on AlN particles. These sintering additives are not only beneficial for promoting densification via the liquid phase sintering process, but they also enhance κ .

Table 4 chronologically shows the development of high thermal conductivity AlN ceramics including sintering aids, sintering methods and conditions and resultant κ values reported between 1973 and 1997. Initial works reported that the κ values of AlN ceramics densified by HP without any additives were limited to $74 \text{ W m}^{-1} \text{ K}^{-1}$ (Slack, 1973; Sakai *et al.*, 1978; Bentsen *et al.*, 1983). After the discovery of effective sintering additives for AlN (Komeya *et al.*, 1981, 1982), the κ values of AlN ceramics were drastically improved; however the developments were step by step as follows:

Table 4 Development of high thermal conductivity AlN ceramics

^aSintering methods abbreviations: HP, Hot-pressing; PLS, Pressureless sintering.

- (1) With the same amount of 0.5 wt% CaO, PLS gave higher κ values than HP (Kuramoto and Taniguchi, 1984; Kuramoto *et al.*, 1985),
- (2) Commercial high purity submicron AlN powders with low oxygen content (1.0 wt%) were synthesized by the carbothermal-reduction and nitridation of Al_2O_3 , and enabled the fabrication of translucent AlN ceramics by PLS with 1.0 wt% CaO (Kuramoto *et al.*, 1985),
- (3) Although the addition of about 1 wt% CaO or Y_2O_3 was enough to densify AlN ceramics, it was found that the further addition of sintering additives, depending on the oxygen content of raw AlN powders, drastically improved the conductivity, which was determined by the composition of the grain boundary phases (Shinozaki and Tsuge, 1986),
- (4) During the heat-treatments of AlN ceramics in the reducing N_2 atmosphere, which were achieved by: (a) using CaC_2 addition (Kurokawa *et al.*, 1988), (b) mixing CF_4 gas (Fujimoto and Ueda, 1988) and (c) heat-treatment in a graphite sagger (Okamoto *et al.*, 1989), the grain-boundary phases containing higher oxygen content migrate to the surface of AlN specimens resulting in lower oxygen content inside the specimens.

Following these developments, the highest κ value, $270 \text{ W m}^{-1} \text{ K}^{-1}$, was finally achieved for AlN ceramics (Horiguchi and Ueno, 1989), which is about 85% of the intrinsic κ of AlN crystals (Slack, 1987).

Thermodynamic, kinetic and microstructural effects of oxygen removal on the thermal conductivity of AlN ceramics were discussed by Virkar *et al.* (1989), Buhr *et al.* (1991) and Jackson *et al.* (1997). In the case of Y_2O_3 addition, a possible reaction during firing is considered as follows,

Oxygen atoms dissolved in the AlN grains diffuse to grain-boundaries, in order to produce stable Al-Y-O compounds. If their free energies of formation are sufficiently low, the grain-boundary phases trap oxygen impurities, and the concentration of oxygen impurity in the AlN grain would be reduced significantly. The different yttrium aluminates, $\text{Y}_4\text{Al}_2\text{O}_9$ (YAM), YAlO_3 (YAP) and $\text{Y}_3\text{Al}_5\text{O}_{12}$ (YAG) phases are stable at high temperature. Fig. 4 shows a quaternary phase diagram for the system: $\text{Al}_4\text{N}_4\text{-Al}_4\text{O}_6\text{-Y}_4\text{O}_6\text{-Y}_4\text{N}_4$. The activity of Al_2O_3 in the three phase fields may be deduced from the $\text{Y}_2\text{O}_3\text{-Al}_2\text{O}_3$ pseudobinary (Adylov *et al.*, 1988). With increasing amounts of Y_2O_3 , the grain-boundary phase changes from YAG to YAP to YAM, the lattice oxygen content decreases, and hence, the thermal resistivity decreases linearly as shown in Fig. 5 (Buhr *et al.*, 1991). When both YAP and YAM phases were present (field III), the highest thermal conductivity was achieved (Jackson *et al.*, 1997).

During the heat-treatment under the reducing N_2 atmosphere, the following reactions were identified (Okamoto *et al.*, 1989);

Fig. 4 Quaternary phase diagram for the system: $\text{Al}_4\text{N}_4\text{-Al}_4\text{O}_6\text{-Y}_4\text{O}_6\text{-Y}_4\text{N}_4$. The $\text{Y}_4\text{Al}_2\text{O}_9$, YAlO_3 and $\text{Y}_3\text{Al}_5\text{O}_{12}$ phases are designated as YAM, YAP and YAG, respectively. Fields I, II, III and IV designate AlN-AION-YAG , AlN-YAG-YAP , AlN-YAP-YAM and $\text{AlN-YAM-Y}_2\text{O}_3$ pseudo-ternary systems, respectively.

Fig. 5 Thermal resistivity at room temperature as a function of the oxygen content in the AlN lattice. Line represents correlation in single-phase AlN ceramics. Sample series a, b and c represent sintering conditions. Series a and b are AlN with Y_2O_3 contents in the range from 0.2 to 8 wt%; for series a and b, respectively, samples sintered at 1750 and 1790°C, using heating rates of 30 and 16 K/min, sintering time = 1 and 3 hrs. Series c are additional samples with Y_2O_3 contents of 1 and 5 wt% sintered under slightly different conditions. Adapted from Slack, G.A., 1973. Nonmetallic crystals with high thermal conductivity. *Journal of Physics Chemistry of Solids* 34, 321–335.

The initial grain-boundary phase, YAM, which existed mainly as a grain boundary film, was decomposed to Y_2O_3 according to Eq. (6) and migrated to the triple junctions in conjunction with grain growth as shown in Fig. 6 (Okamoto *et al.*, 1989). In addition to the compositional change of the grain boundary phases, their morphological change associated with grain growth further enhanced the κ values of AlN ceramics from $199 \text{ W m}^{-1} \text{ K}^{-1}$ to $266 \text{ W m}^{-1} \text{ K}^{-1}$ during heat-treatment at 1900°C for (a) 1 h and (b) 24 h, respectively. The grain-boundary phase migrated to the surface of AlN specimens and finally YN was formed on the specimen surface (Yagi *et al.*, 1989).

Fig. 6 SEM photographs of polished surface (upper row) and TEM electron diffraction patterns (lower row) of AlN ceramics sintered at 1900°C for (a) 1 h and (b) 24 h, respectively.

Effects of transition-metal compounds on the thermal conductivity of AlN sintered with 3 wt% Y_2O_3 were studied, and it was found that the thermal conductivity was influenced by oxygen release from the transition metal oxides, but not by the existence of transition-metal compounds, TiN, ZrN, TaC NbC, and W, all within 0.3 wt% (Kasori *et al.*, 1994). Effects of a variety of lanthanide oxide additives were also investigated, and no significant difference was observed between Y_2O_3 and Ln_2O_3 ($\text{Ln} = \text{La, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm, Yb}$ and Lu) except $\text{Ln} = \text{Ce}$ and Eu which significantly deteriorated densification (Jackson *et al.*, 1997).

Silicon Nitride

In Silicon Nitride (Si_3N_4), there are two stable crystalline structures designated as α and β . Both structures consist of SiN_4 tetrahedra forming a corner-shared three-dimensional network with the characteristic (0001) plane of a hexagonal unit cell with a similar a -dimension but with the c -dimension of α about twice that of β . However, the stacking of the planes are different: in β the sheets are stacked periodically ABABABAB, with large diameter channels parallel to the c -axis; in α the stacking sequence is ABCDABCD with the CD sheets rotated with respect to AB by 180° about the c -axis (Hardie and Jack, 1957). As with SiC and AlN, due to the low self-diffusion coefficients, sintering additives must be used for densifying Si_3N_4 ceramics. It was first found that Si_3N_4 powder could be densified completely by hot-pressing with a second phase additive, MgO (Deeley *et al.*, 1961). It was suggested that MgO reacted with SiO_2 that is normally present on the surface of Si_3N_4 particles to form a magnesium silicate liquid phase at $>1550^\circ\text{C}$ (Terwilliger and Lange, 1974). Later it was shown that the liquid phase is an oxynitride liquid and promotes not only densification, but also the α to β phase transformation (Hampshire and Jack, 1981; Kitayama *et al.*, 1998b). Commercial Si_3N_4 powders mainly consist of α - Si_3N_4 and a small amount of β : the α - Si_3N_4 dissolves into the liquid phase during sintering and precipitates onto β - Si_3N_4 , which develops the interlocking microstructure of elongated β - Si_3N_4 grains and enhances the fracture toughness of this material (Lange, 1973) through the crack-bridging mechanism (Becher, 1991). Since the early research,

numerous studies have been conducted, and alkaline-earth oxides, Al_2O_3 , and rare-earth oxides including Y_2O_3 and lanthanide oxides were found to be effective sintering additives for Si_3N_4 (Negita 1985a,b; Tsuge *et al.*, 1989). After sintering, the liquid phase remains at triple points or along the matrix grain boundaries as a glassy phase or crystalline phases, the volume fractions of which are typically up to 10%.

Table 5 shows chronologically the development of high thermal conductivity Si_3N_4 ceramics including sintering aids, sintering methods and conditions and resultant κ values reported. Initial works reported that the κ values of Si_3N_4 ceramics densified by HP with MgO were limited to $40 \text{ W m}^{-1}\text{K}^{-1}$ (Ziegler and Hasselman, 1981; Tsukuma *et al.*, 1981). The reaction-bonding (RB) technique initially produced Si_3N_4 ceramics with a κ value as low as $17 \text{ W m}^{-1}\text{K}^{-1}$ due to high porosity (Hayashi *et al.*, 1986). It is well recognized that the use of Al_2O_3 , one of the most beneficial sintering additives for Si_3N_4 , considerably lowers thermal conductivity (Watari *et al.*, 1989) because Al_2O_3 reacts with Si_3N_4 to form the solid solution of $\beta\text{-Si}_3\text{N}_4$, $\beta\text{-Sialon}$, which has the chemical formula, $\text{Si}_{6-z}\text{Al}_z\text{O}_z\text{N}_{8-z}$ ($0 < z < 4.2$). Thus, alkaline-earth oxides and rare-earth oxides including Y_2O_3 and lanthanide oxides (Watari, 2001), which had no solid solubility in the Si_3N_4 crystal lattice, were solely used or combined to form the eutectic mixtures for lowering the sintering temperature, because Si_3N_4 decomposes at elevated temperature $> 1850^{\circ}\text{C}$ under normal pressure (Greskovich and Prochazka, 1981). In addition, pressure-assisted sintering methods such as hot-pressing (HP), hot-isostatic pressing (HIP) and, especially, gas-pressure sintering (GPS) (Mitomo and Uenosono, 1991) to suppress the thermal

decomposition of Si_3N_4 were basically used for fabricating dense Si_3N_4 ceramics. Commercial Si_3N_4 ceramics fabricated by GPS achieved high thermal conductivity of $\sim 80 \text{ W m}^{-1} \text{ K}^{-1}$ (Li *et al.*, 1992).

As in the case of AlN ceramics, the development of high thermal conductivity Si_3N_4 ceramics was step by step as follows:

- (1) A silicon-imide thermal decomposition method provided high-purity, fine $\alpha\text{-Si}_3\text{N}_4$ powders (Yamada, 1993), which reduced firing temperature for densification, and increased the conductivity of sintered materials.
- (2) Grain growth of $\beta\text{-Si}_3\text{N}_4$ promoted by prolonged annealing time or extremely high annealing temperature through the solution-precipitation process in the liquid phase (Kitayama *et al.*, 1998a) to form purified $\beta\text{-Si}_3\text{N}_4$ grains, which effectively improved thermal conductivity beyond $100 \text{ W m}^{-1} \text{ K}^{-1}$ (Hirosaki *et al.*, 1993; Hirao *et al.*, 1996; Watari *et al.*, 1999; Akimune *et al.*, 1999; Hayashi *et al.*, 2001a).
- (3) Using non-oxide sintering additives, the native SiO_2 on the raw Si_3N_4 particles were effectively removed to enhance thermal conductivity to $140 \text{ W m}^{-1} \text{ K}^{-1}$ (Hayashi *et al.*, 2001b).
- (4) Development of a new sintering process, sintering of reaction-bonded silicon nitride (SRBSN), initially using Si powder with low oxygen content (0.28 wt%) as a starting material which further improved thermal conductivity (Zhu *et al.*, 2004, 2006, 2007; Zhou *et al.*, 2008, 2011, 2019). The highest thermal conductivity reported for $\beta\text{-Si}_3\text{N}_4$ ceramics was finally achieved up to $182 \text{ W m}^{-1} \text{ K}^{-1}$ after the post-sintering at 1900°C for 60 hrs and subsequent slow cooling at a rate of $0.2^\circ\text{C min}^{-1}$ maintaining its excellent mechanical properties, bending strength of 720 MPa and fracture toughness of $11 \text{ MPa m}^{1/2}$ (Hirao *et al.*, 2017).

In the second stage, high-purity $\beta\text{-Si}_3\text{N}_4$ seed crystals (Hirao *et al.*, 1993) were added to the raw fine $\alpha\text{-Si}_3\text{N}_4$ powder, and subsequent tape-casting or extrusion molding processes rendered the grains arranged in one direction. Through the Ostwald ripening process, the seed crystals preferentially were grown to give textured microstructure composed of large rod-like $\beta\text{-Si}_3\text{N}_4$ crystals in a fine matrix, which achieved the anisotropic thermal conductivity of $120\text{--}162 \text{ W m}^{-1} \text{ K}^{-1}$ parallel to the rod-like crystals and $52\text{--}85 \text{ W m}^{-1} \text{ K}^{-1}$ perpendicular to them; however, the average values in the three directions were limited to $85\text{--}111 \text{ W m}^{-1} \text{ K}^{-1}$ (Hirao *et al.*, 1996; Watari *et al.*, 1999; Akimune *et al.*, 1999) even though the prolonged annealing times or extremely high temperatures would certainly increase the production cost of this material. This became the strong motivation for searching the fundamental understanding about the thermal conductivity of $\beta\text{-Si}_3\text{N}_4$ ceramics (Kitayama *et al.*, 1999a,b, 2000, 2001), which are briefly described in the following sub-sections.

Effect of Microstructure

Based on experimental results, Hirosaki *et al.* (1996a,b) stressed the possibility that the amount of grain boundary film that was directly related to grain size might have a significant influence on the thermal conductivity of $\beta\text{-Si}_3\text{N}_4$. This is because the grain boundary phases in Si_3N_4 ceramics are mainly composed of a SiO_2 -rich oxynitride glassy phase with thermal conductivity as low as $\sim 0.5\text{--}1 \text{ W m}^{-1} \text{ K}^{-1}$, which is much lower than those of the crystalline grain boundary phases in AlN ceramics in the range $2.5\text{--}13 \text{ W m}^{-1} \text{ K}^{-1}$ (Jackson *et al.*, 1997).

Buhr and Müller (1993) treated the thermal conductivity of AlN using simple cubic models with thin grain boundary films, and with or without the continuous network of secondary phases along grain edges. Calculated thermal conductivities were in good agreement with the measured values of AlN sintered bodies with the two types of microstructures mentioned above (Buhr and Müller, 1993; Kim *et al.*, 1996). Due to the isotropic grain shape of AlN, simple cubic models successfully simulated the thermal conductivity of this material. Although the grain boundary film thickness was taken into account in their model, grain anisotropy was not considered so that it is not applicable to $\beta\text{-Si}_3\text{N}_4$ with highly anisotropic grain shape. The strong faceting tendency of the liquid phase sintered Si_3N_4 further complicated the modeling of the thermal conductivity of $\beta\text{-Si}_3\text{N}_4$. Even though the distance between two crystals is in equilibrium (typically 1–2 nm) at some parts of the crystals (Clarke and Thomas, 1977), other parts should have much larger distances due to the faceting of the prismatic planes of $\beta\text{-Si}_3\text{N}_4$ because the two elongated grains are generally not parallel but inclined to each other as in Fig. 7 (Kitayama *et al.*, 1999b). The parts of grain boundaries pointed to by open arrows are very thin and would have the equilibrium grain boundary thickness. In contrast, the other parts pointed to by filled arrows have much larger width than those pointed to by open arrows due to the faceting of the prismatic planes of $\beta\text{-Si}_3\text{N}_4$, which was referred to as the “thick film” in contrast to the thin film in equilibrium. Calculations based on a simple modified Wiener’s model (Wiener, 1904) for thermal conductivity of a composite material predicted that the thermal conductivity of $\beta\text{-Si}_3\text{N}_4$ quickly decreased as the grain boundary film thickness increased in a range of a few tenths of a nanometer, and also that it steeply increased initially with the increase of grain size, and then reached almost constant values as shown in Fig. 8. Theoretically and experimentally, it was demonstrated that mere grain growth would have little effect for improving the thermal conductivity of $\beta\text{-Si}_3\text{N}_4$ (Kitayama *et al.*, 1999b).

Effect of the Lattice Oxygen

Until the end of the 20th century, it was not known whether oxygen dissolved in the $\beta\text{-Si}_3\text{N}_4$ crystal lattice and, if so, how much, although several oxygen contents in the $\alpha\text{-Si}_3\text{N}_4$ crystal lattice were reported: 0.31–0.53 wt% for those prepared by the nitridation of silicon (Edwards *et al.*, 1974) and 0.05–0.30 wt% for those prepared by chemical vapor deposition (Priest *et al.*, 1973; Kijima *et al.*, 1975), for example. Two kinds of pure $\beta\text{-Si}_3\text{N}_4$ crystal powders were prepared by heat treatment of $\alpha\text{-Si}_3\text{N}_4$ powder with sintering additives of $\text{Y}_2\text{O}_3\text{:SiO}_2 = 1\text{:}2$ and $2\text{:}1$ molar ratios. After the secondary phase was removed through acid treatments, their

Fig. 7 SEM photographs of β - Si_3N_4 fabricated by hot-pressing at 1800°C for 2 h and subsequent heat-treatment at 1850°C for 4 h: (a) polished and etched plane parallel to hot-pressed surface, and (b) enlarged image of (a). Note that parts of grain boundary indicated by open arrows are very thin with equilibrium thickness, and those indicated by filled arrows are much wider because of faceting of prismatic planes of β - Si_3N_4 .

Fig. 8 Effect of grain size on the thermal conductivity of β - Si_3N_4 with various grain-boundary film thickness $\delta = 1, 10$ and 50 nm. Calculations were performed using the aspect ratio $= 5$ and the volume fraction of grain boundary phase $= 6\%$. 'Para' and 'Perp' mean thermal conductivities parallel and perpendicular, respectively, to the hot-press direction.

oxygen contents were determined by the hot-gas extraction method (Thomas and Müller, 1991) giving 0.258 and 0.158 wt%, respectively, which were comparable to α - Si_3N_4 as well as AlN (Kitayama *et al.*, 1999c).

As described in the previous section, the ratio of Y_2O_3 and Al_2O_3 in the grain boundary phase was crucial for controlling the lattice oxygen content, and hence, the thermal conductivity of AlN ceramics (Buhr *et al.*, 1991). Thus, it was readily expected that the ratio of Y_2O_3 and SiO_2 derived from the oxygen impurities in the raw powder would control the lattice oxygen content, and hence, the thermal conductivity of β - Si_3N_4 ceramics. Commercial α - Si_3N_4 powder (oxygen content 0.84 wt%) was mixed with Y_2O_3 and SiO_2 powders using the molar ratios of $\text{Si}_3\text{N}_4\text{:Y}_2\text{O}_3\text{:SiO}_2 = 40\text{:}1\text{:}2, 40\text{:}2\text{:}1, 40\text{:}2.5\text{:}0.5$ and $40\text{:}3\text{:}0$, designated Y1, Y2, Y3 and Y4, respectively. After CIPing, powder compacts were hot-pressed at 1800°C for 2 hrs and subsequently annealed at 1850°C for 4 hrs under a nitrogen pressure of 1 MPa. Considering oxygen impurity contained in the raw α - Si_3N_4 powder, corrected $\text{Y}_2\text{O}_3/\text{SiO}_2$ ratios were 0.289, 0.807, 1.267 and 2.029 for Y1, Y2, Y3 and Y4. The grain boundary phases in these specimens were identified using XRD, and it was confirmed that Y1 was in the phase field I, Y2 was in the phase field II, and Y3 and Y4 were in the phase field III shown in Fig. 9 (Kitayama *et al.*, 2000). It was found that a significant increase in thermal conductivity takes place at the critical ratio $\text{Y}_2\text{O}_3/\text{SiO}_2 = 1$ as shown in Fig. 10, which closely correlated to the oxygen contents of 0.400, 0.185, 0.064 and 0.058 wt% for the specimens Y1, Y2, Y3 and Y4, respectively. Thus, it was concluded that the phase composition of the grain boundary dictated the lattice oxygen content of β - Si_3N_4 , and that there was an

Fig. 9 $\text{Si}_3\text{N}_4\text{-Y}_2\text{O}_3\text{-SiO}_2$ phase diagram at 1850°C , constructed schematically from the XRD phase-identification result. $\text{Y}_2\text{O}_3/\text{SiO}_2$ ratios of samples Y1-Y4 are indicated by arrows.

Fig. 10 Relationship between the $\text{Y}_2\text{O}_3/\text{SiO}_2$ ratios and thermal conductivities of samples Y1-Y4.

Fig. 11 Relationships between ionic radii of rare-earth oxide additives and (a) the lattice oxygen contents and (b) thermal conductivities of β -Si₃N₄ annealed at 1850°C for 4 and 16 hrs. 'Para' and 'Perp' mean thermal conductivities parallel and perpendicular, respectively, to the hot-press direction.

optimum amount of Y_2O_3 addition, depending on the amount of oxygen impurity in the raw Si_3N_4 powder, to achieve the highest thermal conductivity in β - Si_3N_4 just as in the case of AlN ceramics.

Effect of Rare-earth Oxide Additives

Rare-earth elements including Sc, Y and lanthanides (Ln) have a common ionic valence z of $+3$ and are known to be the most electro-positive elements. Thus, it was suggested that they are suitable sintering additives for Si_3N_4 (Negita, 1985a,b). Because the ionic radius r of lanthanide elements continuously decreases with increasing atomic number – known as the lanthanide contraction – the cationic field strength z/r^2 also continuously changes with the atomic number, which causes substantial variations in the thermal and physical properties of Ln-Si-(Al)-O-N glasses (Shelby and Kohli, 1990; Tanabe *et al.*, 1992; Ohashi *et al.*, 1995; Ramesh *et al.*, 1997). These glasses are similar to the grain boundary amorphous phases in Si_3N_4 ceramics sintered with rare-earth oxide additives, and thus, they should affect various properties of Si_3N_4 ceramics themselves. It was observed that the mean aspect ratio of β grains at the end of the α to β phase transformation was proportional to the ionic radius of the rare-earth elements (Hoffmann, 1994), and also that rare-earth elements strongly influenced grain growth behavior not only during the phase transformation but also during the Ostwald ripening (Kitayama *et al.*, 1999c). These works clearly demonstrated that rare-earth oxide additives significantly affected the grain growth behavior of Si_3N_4 during and after the phase transformation, which would influence the purification kinetics of the β - Si_3N_4 crystal lattice that proceed via the solution-precipitation mechanism through the liquid phase. Although a series of different rare-earth oxide additives had no significant effect on thermal conductivity of AlN (Jackson *et al.*, 1997), there were significant differences for β - Si_3N_4 (Kitayama *et al.*, 2001).

Commercial α - Si_3N_4 powder (oxygen content 0.84 wt%) was mixed with RE_2O_3 powders ($RE = La, Nd, Gd, Y, Yb$, and Sc) using the molar ratios of $Si_3N_4:RE_2O_3 = 20:1:2$. After CIPing, powder compacts were hot-pressed at $1800^\circ C$ for 2 hrs and subsequently annealed at $1850^\circ C$ for 4 and 16 hrs under a nitrogen pressure of 1 MPa. Only a sample sintered with La_2O_3 at $1850^\circ C$ for 4hrs contained a significant amount of the α -phase, and none of the other samples contained α -phase. In addition to the amorphous grain boundary phase, a variety of crystalline phases were observed for different rare-earth oxide additives. For Sc_2O_3 , only Sc_2SiO_5 ($RE_2O_3:SiO_2 = 1:1$) was identified. For La_2O_3 , both $La_{20}N_4Si_{12}O_{48}$ ($RE_2O_3:SiO_2 = 10:9$) and La_2SiO_5 ($RE_2O_3:SiO_2 = 1:1$) were identified. For Nd_2O_3 , both $Nd_2Si_3O_3N_4$ ($RE_2O_3:SiO_2 = 1:0$) and $Nd_4Si_3O_{12}$ ($RE_2O_3:SiO_2 = 2:3$) were identified. For Y_2O_3 and Gd_2O_3 , both $RE_{20}N_4Si_{12}O_{48}$ ($RE_2O_3:SiO_2 = 10:9$) and $RE_2Si_3O_3N_4$ ($RE_2O_3:SiO_2 = 1:0$) were identified. For Yb_2O_3 , only $Yb_4Si_2N_2O_7$ ($RE_2O_3:SiO_2 = 4:1$) was identified. Evidently, grain size markedly increased as the ionic radius of the rare-earths decreased from La to Nd to Gd, and reached almost a constant level at lower ionic radius. Relationships between ionic radii of rare-earths from the oxide additives and lattice oxygen contents (Fig. 11(a)), and also thermal conductivities (Fig. 11(b)) demonstrated that thermal conductivity showed a good inverse correlation with lattice oxygen content. Thus, unlike AlN, the ionic radius of the particular rare-earth element significantly influenced the phase transformation kinetics (Kitayama *et al.*, 2006), grain growth behavior, grain boundary phase, lattice oxygen content and hence thermal conductivity of β - Si_3N_4 , which was reasonably explained by the different interfacial adsorption behaviors of rare-earth ions (Urakami *et al.*, 2017).

Summary

As described in the introduction, the world-wide trend for power electronics has created a strong demand for high thermal conductivity ceramics. After the prediction made by Slack (1973), the thermal conductivities of SiC and AlN ceramics were improved very significantly. However, no further developments occurred after 1990 as shown in Fig. 1, at which point they had reached about 55% and 85%, respectively, of their intrinsic values. Although there is still room for improvement in SiC, the demand had ceased probably due to the fact that its electrical properties were those of a semiconductor, which renders it unsuitable for application as a substrate material for electronic circuits.

The thermal conductivity of AlN ceramics had reached almost its maximum value; however, its poor mechanical properties had restricted its industrial application. Thus, an alternative high thermal conductivity ceramic candidate with excellent mechanical properties, Si_3N_4 , has been actively developed after the prediction made by Haggerty and Lightfoot (1995). However, the improvement of its thermal conductivity was found to be much more difficult than for AlN mainly due to the amorphous grain boundary phase and the strong faceting nature of the β - Si_3N_4 crystal. Although the recent advancement of high thermal conductivity Si_3N_4 ceramics by the new SRBSN technique using Si powder with low oxygen content as a raw material achieved about 57% of its intrinsic thermal conductivity, assuming the value of $320 \text{ Wm}^{-1} \text{ K}^{-1}$, this achievement still depended on prolonged annealing time at high temperature, which would certainly increase the production cost of this material. Since there is still room for further improvement in Si_3N_4 , efforts for fabricating high thermal conductivity Si_3N_4 ceramics, using lower temperatures and shorter duration for annealing, have been on-going through the optimization of the SRBSN technique (Zhou *et al.*, 2019). Finally, other possibilities are being explored using non-oxide sintering additives such as $ZrSi_2$ (Wang *et al.*, 2020a), YH_2 (Wang *et al.*, 2020b) and $ZrSi_2$ - $MgSiN_2$ (Wang *et al.*, 2020c) as shown in Table 5.

Historical Overview

The MAX or $M_{n+1}AX_n$ phases are a family of compounds within the class of complex or double carbides or nitrides where “M” refers to an early transition metal, “A” to an A-group element, “X” can be C and/or N and “n” is an integer (commonly 1, 2 or 3) as described in Barsoum (2013). Based on the integer n, the MAX phases can be subcategorized into 211, 312 and 413 structures, respectively. New compounds and possible M and A elements are still being discovered and, hence, this family is expanding every month. At the moment, over 155 ternary MAX phase compounds have been experimentally reported, as recently summarized by Sokol *et al.* (2019). This number increases considerably when solid solutions are taken into account.

The name “MAX phase” was introduced around the year 2000 (Barsoum, 2000; Barsoum and El-Raghy, 2001). However, the history of these phases goes back to the early 1950s. To the best of our knowledge, in the first report on these phases, Bloom and Grant (1950) observed the “Cr₂AlC” phase in a Cr-Al-C mixture in an attempt to synthesize the binary CrC. About 10 years later, Kudielka and Rohde (1960) described the crystal structure of a ternary carbide Ti₂SC, observed in steel, reporting that Ti could be replaced by Zr. In the beginning of the 1960s, a systematic study by Jeitschko, Nowotny and Benesovsky revealed that Cr₂AlC and Ti₂SC along with about 30 other ternary transition metal (T) carbides form a set of isomorphous compounds with the general structure “T₂MX,” which they grouped as H(agg)-phases (Nowotny *et al.*, 1964; Jeitschko *et al.*, 1963, 1964a,b,c). Apart from the H-phases, the group of Nowotny also identified two related compounds, i.e., Ti₃SiC₂ (Jeitschko and Nowotny, 1967) and Ti₃GeC₂ (Wolfsgruber *et al.*, 1967). Except for the crystallographic description of these phases, little was known about their properties. Barsoum and El-Raghy (1996) reported on the “remarkable ceramic: Ti₃SiC₂” and demonstrated the attractive properties of this laminated ternary carbide. With the discovery of Ti₄AlN₃ (Barsoum *et al.*, 2004), they concluded that all these phases could be grouped under the formula unit “M_{n+1}AX_n.” Since 2000, “MAX phase” is the common name used to refer to this family of carbides, although some exceptions exist, such as the TAX (Zhou *et al.*, 2013) or T₂MX (Hug, 2006) phases.

Not all combinations of M, A and X elements indicated in Fig. 1 are possible. The elements with a hatched background, i.e., Fe, Cu, Zn, Y, Sb, W and all lanthanides, are actually only reported in solid solutions. On the other hand, some elemental combinations can form several MAX phase orders, e.g., Ti₂GeC, Ti₃GeC₂ and Ti₄GeC₃ are known to exist in the Ti-Ge-C system (Högberg *et al.*, 2005a). From this family of MAX phases, a few ternary combinations have been investigated more extensively, i.e., Ti₃SiC₂, Ti₂AlC, Ti₃AlC₂ and Cr₂AlC. The reason, therefore, is the possibility to synthesize these carbide materials in a nearly phase-pure bulk form using a relative simple process. A first chemically out-of-plane ordered (o-MAX) quaternary 312 (M',M'')₃AlC₂ MAX phase, i.e., (Cr_{2/3},Ti_{1/3})₃AlC₂, was reported in Liu *et al.* (2014). In-plane ordering (i-MAX) was observed in (Mo_{2/3},Sc_{1/3})₂AlC by Tao *et al.* (2017); by Dahlqvist *et al.* (2017); and by Dahlqvist *et al.* (2018). Besides alloying on the M site, alloying on the A (Li *et al.*, 2020) and X (Manoun and Saxena, 2007; Cabioch *et al.*, 2012) sites is also possible. Very recently, the first high entropy MAX (HE-MAX) phase, (Ti_{0.35}Zr_{0.12}Nb_{0.21}Hf_{0.12}Al_{0.19})₂Al_{0.81}C, was reported by Bao *et al.* (2020).

The chemical etching and exfoliating or selective de-intercalation of the MAX phases results in MXenes, which have attracted a tremendous interest since the first report of Naguib *et al.* (2011). Anasori and Gogotsi (2019) contains a detailed overview of the progress in MXene synthesis, characterization and applications.

Structure of $M_{n+1}AX_n$ Phases

Ternary MAX Phases

The $M_{n+1}AX_n$ phases are known to be “nanolaminated solids” and exactly this layered nature provides them with a set of salient properties. The crystal structure of the $M_{n+1}AX_n$ phases is characterized by a hexagonal, anisotropic unit cell of space group 194 (P6₃/mmc) consisting of two formula units. For the three common $M_{n+1}AX_n$ phase types or orders, i.e., 211, 312 and 413, these unit cells are shown in Fig. 2(a)–(c), revealing the origin of the layered structure: n [M₆X]-octahedra are interleaved with an atomic layer of A, where the M-atoms form a trigonal prismatic unit with the A-element in the center. Splitting the lattice this way, the MAX structure is composed of two building blocks: (1) the M₆X-octahedra that are structured in the rock-salt (NaCl-type) configuration and (2) the trigonal prismatic M₆A-units that have an hexagonal closed packing structure (Etzkorn *et al.*, 2007a; Etzkorn *et al.*, 2009; Hug *et al.*, 2005; Hug, 2006). For example, the unit cell of the 211 type is composed of two of each of these building blocks.

In order to completely determine the structure, three lattice parameters have to be refined: the dimensions of the unit cell, *a* and *c*, and the relative height *z_M* of the M-atom with respect to the central layer of carbon, as shown in Figs. 2 and 3. The canonical position of the latter is at 1/12 (0.0833), which corresponds to an equal spacing of the M- and A-planes. The 312 type comprises

Fig. 1 The different M, A and X elements that have been reported in ternary MAX phases. The hatched elements are only reported in quaternary systems.

Fig. 2 Unit cells of (a) M_2AX , (b) M_3AX_2 and (c) M_4AX_3 and (d) a high-resolution STEM image along the $[1\bar{2}10]$ -direction of $(Zr,Ti)_2AlC$.

two M_6X -units that are present between each A-layer, resulting in two non-equivalent M-sites: the M_I -site close to the A-layer and the central M_{II} -site, which is only bonded to M and X. For this type, there are four free variables: a , c , z_X and z_{M_I} . In a similar fashion, the 413 type has five free variables, due to two non-equivalent M- and X-sites (Etzkorn *et al.*, 2007a). Table 1 gives an overview of the atomic positions for the three most common MAX phase orders: 211, 312 (α -312) and 413 (α -413). Of the latter two types, polymorphs exist that involve a shearing of A-layers (β -312 and γ -413) (Wang *et al.*, 2004; He *et al.*, 2011) or restructuring of the MX-block (β -413) (Eklund *et al.*, 2007).

The laminated structure can be visualized clearly using high-resolution transmission scanning electron microscopy (HRSTEM) when looking along the $[1\bar{2}10]$ direction, as illustrated for $(Zr,Ti)_2AlC$ in Fig. 2(d). The M-atoms form a zigzag pattern where the A-layer acts as mirror plane, similar as observed in $(MC)_nAl_3C_2$ and $(MC)_n[Al(Si)]_4C_3$ phases. However, a fundamental difference with the latter is the absence of bonds between A and X. The X atoms are only connected to M-atoms where the M–X bonding is significantly stronger than the M–A bonding (Medvedeva *et al.*, 1998; Zhang and Wang, 2007). The MAX phase bonds are achieved

by hybridization of the M-atom d-states with the X- and A-atom p-states (Hug, 2006; Magnuson *et al.*, 2007), where the M–X bond in the MAX phases shows similar characteristics to the M–X bonds in the corresponding binary carbides. When considering the two building blocks of the 211 type, some steric effect is observed after Kanoun *et al.* (2009). Both the octahedron and the trigonal prism (see Fig. 3) are distorted due to the fact that the M-atom is commonly not on the canonical position and the c/a -ratio deviates from the ideal packing ($c/a = 2\sqrt{6}$) (Hug *et al.*, 2005; Hug, 2006). The distortion of the cubic octahedron, o_d , can be expressed as:

$$o_d = \frac{d_1}{d_2} = \frac{\sqrt{3}}{2\sqrt{4z_M^2\left(\frac{c}{a}\right)^2 + \frac{1}{12}}} \quad (1)$$

And the distortion parameter of the trigonal prism, p_d , is given by:

$$p_d = \frac{d_{M-M}}{d_{M-A}} = \frac{1}{\sqrt{\frac{1}{3} + \left(\frac{1}{4} - z_M\right)^2\left(\frac{c}{a}\right)^2}} \quad (2)$$

For the ideal case, the distortion parameters are equal to 1. In addition, they are known to vary with temperature as Jaouen *et al.* (2013) reported for Cr_2AlC , and are also significantly affected by the chemical composition according to Cabioch *et al.* (2013). However, no direct connection between o_d , p_d and the intrinsic stability of a MAX phase compound has been established, but a correlation between the atomic radii of the M and A elements towards stable MAX phases was proposed by Lapauw *et al.* (2018b). Small M-atoms combine better with small A-atoms and large M-atoms with large A-atoms. This “match” in atomic radii between

M and A can be used as a practical guideline for the synthesis of solid solution MAX phases. The concept of double solid solution $(M', M'')_2(A', A'')C$ was found advantageous in terms of MAX phase synthesis and purity (see Section “Solid Solutions and Ordered MAX Phases”).

Apart from the 3 common MAX phase types, some other rather exceptional structures have been reported. Most of them are grouped by [Hu et al. \(2013\)](#). A first set comprises $M_{n+1}AX_n$ -like structures with $n > 3$, e.g., Ta_6AlC_5 by [Lin et al. \(2006\)](#) and Ti_7SnC_6 by [Zhang et al. \(2009\)](#). These structures were detected during HRTEM investigations in the Ta-Al-C and Ti-Sn-C systems, respectively. However, no significant amount of “phase-pure” material has been reported yet and, therefore, they are not considered as distinct phases ([Eklund et al., 2010](#)). Another set consists of the “hybrid” orders $M_5A_2C_3$ and $M_7A_2C_5$ that are a combination of a 312 atomic stacking sequence with a 211 and 413 order, respectively. These structures have been reported by [Palmquist et al. \(2004\)](#), [Högborg et al. \(2005a\)](#), [Zhou et al. \(2008\)](#), [Scabarozi et al. \(2011\)](#), [Lane et al. \(2012\)](#), [Wang et al. \(2012\)](#) for several systems, e.g., $Ti_5A_2C_3$ with $A = Si, Ge$ and Al . The unit cell consists of three formula units and has been observed over significant distances resulting in clear associated peaks in the XRD pattern.

Another important point to address is the X-element content in the MAX phases. Most of the phases are reported as (near-) stoichiometric compounds, although some reports on sub-stoichiometric X are found in literature, especially 413 phases. The experimentally observed deficiency of N in $Ti_4AlN_{3-\delta}$ is reported to stabilize the structure by [Barsoum et al. \(2000\)](#) and by [Music et al. \(2005\)](#). Also for V_4AlC_{3-x} ([Etzkorn et al., 2007b](#)) and Nb_4AlC_{3-x} ([Zhang et al., 2015b](#)), C-vacancies have been reported, mainly on the central, C_{II} -site (Wyckoff 2a). For the latter, a transition from an ordered (o - $Nb_4AlC_3 - Nb_{12}Al_3C_8$) to disordered Nb_4AlC_{3-x} around $1400^\circ C$ was observed. This is not surprising since the main unit in the 413 types is the M_6X octahedron, identical with the NaCl-type binary carbides. This observation is also true for the corresponding binary carbides, which can be significantly sub-stoichiometric.

Solid Solutions and Ordered MAX Phases

The exploration of quaternary (or higher) systems that crystallize in the MAX structure already started in the 1960s with [Reiffenstein et al. \(1966\)](#), looking merely at the interchangeability of the atoms on the M-site. Nevertheless, the investigation of quaternary and more complex MAX phase based structures is a very active research topic today, in particular due to the fact that they can serve as base material for the synthesis of unique 2D-carbide materials, MXenes, as demonstrated by [Tao et al. \(2017\)](#).

Single-site and double-site solid solutions

[Naguib et al. \(2014\)](#) provide a list of reported MAX phase solid solutions up to 2014, including 34 systems with substitutional solid solutions on the M, A and X-site, whereas the more recent overview by [Sokol et al. \(2019\)](#) contains already 29 $(M', M'')_{n+1}AX_n$ and 15 $M_{n+1}(A', A'')X_n$ single-site solution MAX phases. One of the reasons of interest is the possibility of synthesizing compounds for which one or both of the end-members do not exist, i.e., the elements with the hatched background in [Fig. 1](#). This can even lead to the incorporation of unconventional M- or A-elements such as W ([Yang et al., 2014](#); [Lai et al., 2017](#)) or Fe ([Lin et al., 2016](#)).

The addition of a fourth element can also be beneficial to improve the phase purity of the material, such as the addition of Al to Ti_3SiC_2 in order to avoid the formation of TiC ([Zhu et al., 2004](#)). The addition of a fifth element, targeting the formation of $(M', M'')_{n+1}(A', A'')X_n$ double solid solutions was successfully explored to synthesize near-phase pure MAX phase ceramics. As an example, although Zr_2AlC , Zr_3AlC_2 and Hf_2AlC/Hf_3AlC_2 can be synthesized, as respectively reported by [Lapauw et al. \(2016a,b,c\)](#), it is always present in combination with ZrC/HfC and Zr-Al/Hf-Al intermetallics. Judicious alloying on both M and A sites, however, allowed to produce near-phase pure ($> 99\%$) $(Zr, Nb)_2(Al, Sn)C$ ([Lapauw et al., 2018b](#)) and $(Zr, Ti)_2(Al, Sn)C$ ([Tunca et al., 2019](#)) ceramics. In a similar approach ([Griseri et al., 2020](#)), the $(Ta_{1-x}Hf_x)_4AlC_3$ and $(Ta_{1-x}Nb_x)_4AlC_3$ MAX phase content could be substantially increased by the addition of Sn to form $(Ta_{1-x}Hf_x)_4(Al_{0.5}Sn_{0.5})C_3$ and $(Ta_{1-x}Nb_x)_4(Al_{0.5}Sn_{0.5})C_3$ double solid solutions. Moreover, alloying ternary MAX phases allows tuning of some properties, like the coefficient of thermal expansion (CTE) of $Cr_2(Al, Ge)C$ ([Cabioch et al., 2013](#)), improving the high temperature stability of $(Ti, Zr)_3SiC_2$ ([Wan et al., 2010](#)), increasing the hardness of $(Ti, V)_2AlC$ ([Meng et al., 2005](#)), increasing the toughness, high temperature stiffness and thermal stability of $(Nb, Zr)_4AlC_3$ ([Lapauw et al., 2016d](#)) or altering the magnetic properties of $(Cr, Mn)_2AlC$ ([Mockute et al., 2014](#)) and $V_2(Sn, A)C$ ($A = Fe, Co, Ni, Mn$) ([Li et al., 2020](#)).

In terms of crystal structure, alloying directly affects the lattice parameters a and c . They obey Vegard's law, as proposed by [Vegard \(1921\)](#), meaning that the variation of a and c is linearly dependent on the amount of dopant. However, the effects on a and c can be different, changing the anisotropy of the unit cell and the distortion factors α_d and ρ_d ([Cabioch et al., 2013](#)). The evolution of the other free variable, z_M , in the 211 type, depends on which element is partially replaced. In the case of $(Ti, Nb)_2AlC$, an M-site solid solution, [Hug et al. \(2005\)](#) showed that each M-element would have a different z_M . For $Cr_2(Al, Ge)C$, an A-site solid solution, [Cabioch et al. \(2013\)](#) showed that z_M increased linearly with increasing Al-content. For all the structures listed by [Naguib et al. \(2014\)](#), a statistical distribution of the host and solute atoms was assumed.

o-MAX phases

[Liu et al. \(2014\)](#) demonstrated the synthesis of Cr_2TiAlC_2 , showing a special type of ordering. The Cr-atoms preferentially occupy M_I -sites adjacent to the A-layers, while the Ti-atoms are positioned on the M_{II} -sites in the middle of the MX-block. [Caspi et al. \(2015\)](#)

Fig. 4 (a) EDS-mapping, (b) EDS line scan intensity along the c-direction and (c) HRSTEM image of the solid solution o-MAX phase $(\text{Zr}_{1/3}\text{Ti}_{2/3})_3\text{AlC}_2$.

described the same ordering in the M-atom positions for Cr_2VAlC_2 and $\text{Cr}_2\text{V}_2\text{AlC}_3$. These structures are referred to as o-MAX phases; out-of-plane ordered quaternary $(\text{M}', \text{M}'')_3\text{AX}_2$ or $(\text{M}', \text{M}'')_4\text{AX}_3$ MAX phases with a unique ordering of the M layers, such that two M' layers sandwich either one or two layers of M'' within each M–X block, where M' and M'' are early transition metals. Similarly, $(\text{Mo}_2\text{Ti})\text{AlC}$, $(\text{Mo}, \text{Ti})_2\text{AlC}_3$, $(\text{Mo}_2\text{Sc})\text{AlC}_2$ and $(\text{Ti}_2\text{Zr})\text{AlC}_2$ have been subsequently reported as o-MAX phases by [Anasori et al. \(2014\)](#), [Anasori et al. \(2015a\)](#), [Meshkian et al. \(2017\)](#) and [Tunca et al. \(2019\)](#), respectively. Interestingly, all identified o-MAX phases up to now contain Al as the A-element and C as the X-element. Since no high phase purity bulk o-MAX ceramics have been reported yet, their intrinsic material properties are still unknown.

The fully ordered atomic stacking sequence of $(\text{Zr}_{1/3}\text{Ti}_{2/3})_3\text{AlC}_2$ is shown in [Fig. 4](#). Two main factors responsible for ordering were already addressed by [Hume-Rothery \(1950\)](#), i.e., a clear difference in electronegativity (χ) and in covalent radii. For both factors, the ordering is consistent in all ordered MAX phases so far reported. It appears that the M-element with the smallest atomic radius ($\text{Cr} < \text{V} < \text{Mo} < \text{Ti} < \text{Zr} < \text{Sc}$) and the highest χ ($\text{Mo} > \text{Cr} > \text{V} > \text{Ti} > \text{Sc} > \text{Zr}$) is positioned in the outer-layers of the M_I – M_II – M_I “sandwich” (312 type) or M_I – M_II – M_II – M_I “sandwich” (413 type) next to the A-element layer, whereas the larger and less electronegative M-element is positioned inside the “sandwich” structure on the M_II -sites ([Tunca et al., 2017](#)). For most of the observed ordered systems, one or even both of the end members are not stable and they should be differentiated from the random solid solution. A unique exception is $(\text{Zr}_{1/3}\text{Ti}_{2/3})_3\text{AlC}_2$, which can claim the double label of solid solution and ordered phase ([Tunca et al., 2017](#)).

Different types of ordering have been reported by [Tao et al. \(2016\)](#). A first type was observed during the thin film deposition of $(\text{Mn}, \text{V})_3\text{GaC}_2$, where the different M-elements tend to cluster in separate M_3C_2 -blocks forming an alternated pattern of V-rich M_3C_2 -layers with Mn-rich M_3C_2 -layers interleaved by a plane of Ga-atoms.

i-MAX phases

The discovery of $(\text{Mo}_{2/3}\text{Sc}_{1/3})_2\text{AlC}$ revealed a new type of ordering, the so-called i-MAX phase. This MAX phase compound has a 211 stoichiometry and exhibits an in-plane order of the M-elements. In “conventional” 211-type MAX structures, there is only one M-site which is statistically occupied by the different M-elements in $(\text{M}', \text{M}'')_2\text{AX}$ solid solutions. The description of the i-MAX crystal structure consists of a more complex unit cell, extended in-plane along a and b , with non-equivalent M-sites where the monoclinic (space group 15 – $\text{C}2/c$) and orthorhombic (space group 63 – Cmcm) descriptions show equal stability. Next to $(\text{Mo}_{2/3}\text{Sc}_{1/3})_2\text{AlC}$, $(\text{V}_{2/3}\text{Zr}_{1/3})_2\text{AlC}$, $(\text{Mo}_{2/3}\text{Y}_{1/3})_2\text{AlC}$ and $(\text{Cr}_{2/3}\text{Zr}_{1/3})_2\text{AlC}$ have been identified as i-MAX phases by [Dahlqvist et al. \(2017\)](#) and [Chen et al. \(2018\)](#). The structure of $(\text{Cr}_{2/3}\text{Zr}_{1/3})_2\text{AlC}$ is displayed in [Fig. 5](#). HRSTEM and selected area electron diffraction (SAED) reveal the atomic stacking sequence along the $[110]$ and $[100]$ zone axes of the monoclinic structure. This structure was discovered by a close interplay of experimental synthesis and characterization followed by a computational assessment of the stability using density functional theory (DFT).

Due to the possibility of making the attractive MXene 2D-derivative, the theoretical possibility to form ordered MAX phases has been predicted for 24 structures by [Anasori et al. \(2015b\)](#). In these calculations, two important parameters have to be considered: the formation enthalpy (ΔH_cp) of these phases should be lower than for all other competing phases, underlying the importance of including all possible phases, even hypothetical phases ([Dahlqvist et al., 2010](#); [Tao et al., 2017](#)). The second parameter is the order-to-disorder transition temperature (T_disorder), which takes into account the configurational entropy ([Dahlqvist and Rosen, 2015](#)). Above T_disorder , the disordered structure is most favorable. In order to experimentally obtain an ordered structure, it is suggested that T_disorder should be higher than the synthesis temperature.

[Sokol et al. \(2019\)](#) provides an overview of about 30 i-MAX phases that have already been discovered, including rare-earth containing phases, which have been reported for the first time by [Tao et al. \(2019\)](#). Interestingly, all identified i-MAX phases have been synthesized with Al or Ga as the A-element, and C as the X-element. Since no high phase purity bulk i-MAX ceramics have been reported yet, their intrinsic material properties are still unknown.

MAX Phase Synthesis

Synthesis Methods

Regarding the synthesis of MAX phase ceramics, it should be highlighted that there are very few commercial MAX phase powder sources available at present and limited to the Ti_3SiC_2 , Ti_2AlC , Ti_3AlC_2 , V_2AlC and Nb_2AlC compositions, whereas bulk MAX phase ceramics, as far as we know, are not available on the market at present. MAX phase synthesis can be divided into powder, bulk, and thin film synthesis.

MAX phase powders

Amongst the powder production routes are self-propagating high temperature synthesis (SHS) (Yeh and Yang, 2013) used for the Maxthal® 211 and 312 production, microwave synthesis (Hamm *et al.*, 2016) and via molten salts (Tian *et al.*, 2008). MAX phase powders can be obtained by molten salt synthesis from elemental powders. Ti_2AlC , Ti_3AlC_2 , Cr_2AlC and other phases, for example, can be obtained in molten KBr (Dash *et al.*, 2019), Cr_2AlC can be synthesized in NaCl/KCl mixtures (Tian *et al.*, 2008), and Ti_2AlC and Ti_3AlC_2 powder can be produced in molten NaCl and/or KCl (Galvin *et al.*, 2018; Yang *et al.*, 2019). Electrosynthesis of MAX phase powder from an oxide/carbon precursor in molten salt is also possible. Ti_3AlC_2 powder can be made from a $\text{TiO}_2/\text{Al}_2\text{O}_3/\text{C}$ precursor pellet (cathode) at 900°C and 3.1 V in molten CaCl_2 (Li *et al.*, 2018), whereas Cr_2AlC powder can be obtained from a $\text{Cr}_2\text{O}_3/\text{Al}_2\text{O}_3/\text{C}$ precursor pellet (cathode) at 700°C and 3 V in molten NaCl- CaCl_2 (Abdelkader, 2016). MAX phase powder can alternatively be obtained by comminution of bulk material processed by reactive synthesis.

MAX phase coatings

From the thin film perspective, mainly three types of deposition techniques have been used: physical vapor deposition (PVD) via elemental dc sputtering (Högborg *et al.*, 2005b), cathodic arc deposition (Rosen *et al.*, 2007) or magnetron sputtering (Walter *et al.*, 2006; Furgeaud *et al.*, 2019) and chemical vapor deposition (CVD) (Pickering *et al.*, 2000), as well as solid-state reaction synthesis between thin films or at a film-bulk interface (Eklund *et al.*, 2017). A comprehensive review on MAX phase thin films is provided by Eklund *et al.*, (2010). Of special interest is the synthesis of new MAX phase coatings by a thermal substitution reaction of a Ti_3SiC_2 coating with noble metals like Au and Ir forming Ti_3AuC_2 , $\text{Ti}_3\text{Au}_2\text{C}_2$ and Ti_3IrC_2 coatings (Fashandi *et al.*, 2017).

Comparing bulk and thin film processing, some clear differences can be identified. Primarily, the synthesis temperature is different. MAX phase formation occurs at significantly lower temperatures in case of thin films, e.g., PVD of Cr_2AlC at 450°C (Eklund *et al.*, 2010), whereas a temperature in the range of 1200–1400°C is reported for bulk synthesis by Wang and Zhou (2010). The difference is caused by the additional energetic flux originating from the atomic bombardment. A second difference is the thermodynamic state of the formed material. For most bulk techniques, a near-equilibrium state is considered. Hence, the produced MAX phases are assumed to be more stable than the competing phases. For some thin film processes, MAX phase compounds marked as “meta-stable,” such as Ti_4SiC_3 (Palmquist *et al.*, 2004), Ti_4GeC_3 (Högborg *et al.*, 2005a) and Ti_3SnC_2 (Högborg *et al.*, 2006), could be deposited. These MAX phases are considered intrinsically stable in terms of the Cauchy-Born criterion, but are difficult to synthesize in bulk where the formation of Ti_4SiC_3 is only observed using a very specific technique (Istomin *et al.*, 2016) or in the case of Ti_3SnC_2 by including some specific additives (Dubois *et al.*, 2007). Similarly, Ingason *et al.* (2013) reported the thin film synthesis of the magnetic MAX phase Mn_2GaC . Despite the interest in magnetic MAX phases, Mn_2GaC has not been synthesized in bulk to date.

MAX phase bulk ceramics

Bulk processing of MAX phase ceramics is predominantly achieved by powder metallurgy and requires an intimate contact between the starting powder constituents. These methods include conventional (CS) or microwave sintering under protective atmosphere (Hamm *et al.*, 2016; Wang *et al.*, 2014), hot isostatic pressing (HIP) (Barsoum and El-Raghy, 1996), hot pressing (HP) (Hu, Li *et al.*, 2007), spark plasma sintering (SPS) (Tian *et al.*, 2007a), single crystal growth (Etzkorn *et al.*, 2009), and mechanical alloying (MA) Li and Zhai (2005). The synthesis protocols of the most common layered carbide and nitride MAX phases were reviewed by Haemers *et al.* (2020). Bulk synthesis techniques can be subdivided in processes that follow a pressureless synthesis route (e.g., CS and SHS), and others that are associated with pressure-assisted sintering techniques (e.g., HIP, HP and SPS). The latter group seems more successful in terms of being able to synthesize the different members of the MAX phase family, especially considering the higher orders. Nb_4AlC_3 has only been reported by HP or SPS synthesis. $\text{M}_{n+1}\text{AX}_n$ phases with a higher n require a higher formation temperature compared to MAX phases with a smaller M_{n+1}X_n layer in the same ternary system. Hence, it is possible to obtain Ti_3AlC_2 , Nb_4AlC_3 and Ta_4AlC_3 by annealing the 211-phase containing materials in the corresponding ternary systems (Eklund *et al.*, 2010). However, at high temperature, MAX phase decomposition occurs as a competing reaction:

The weakest bond in the MAX phases is the M–A bond, which is also the first one to break at elevated temperature, followed by outward diffusion of the A-element. One of the advantages of the pressure-assisted techniques lies in the fact that the material is encapsulated in a die/punch system (HP and SPS) or metal capsule (HIP) that minimizes the loss of the A-element. This claim is supported by Lu and Zhou (2010), where the ternary powder mixture is embedded in Al_4C_3 , which significantly improved the amount of Ti_3AlC_2 formed during pressureless sintering.

As basis for the discussion of the various synthesis routes and the different process parameters, the ternary Ti–Al–C system is selected, since it contains two of the most investigated MAX phases, i.e., Ti_2AlC and Ti_3AlC_2 . The most economical way to produce MAX phases is by self-propagating high temperature synthesis (SHS), as it is time and energy effective, requires limited infrastructure and can be performed on an industrial scale. The formation of MAX phase compounds is exothermal and can be self-sustainable. The powder bed is ignited and a reaction front propagates through the powder bed converting the starting powder into the reaction products. A high MAX phase content can be obtained in this way, but there are often competing phases present, such as TiC (Liu *et al.*, 2007). This method commonly uses pure elemental powders as starting material. Other combinations have been reported, such as a mixture of M-oxides, Al and Al_4C_3 to form $(\text{Ti,V})_2\text{AlC}$ solid solution and Al_2O_3 by aluminothermal

reduction of the M-oxides (Yeh and Yang, 2013). This method is commercially viable, but control of the process and, hence, the final product is limited. Moreover, only a limited number, mainly 211 types, of MAX phases synthesized by SHS have been reported, and an additional densification step is required to produce mechanical components.

Conventional sintering provides better process control and is used for several MAX phase systems. A powder compact composed of the elemental powders is heated under a protective atmosphere or in vacuum and held for a certain amount of time. This method is also cost effective and easily facilitates upscaling. It has been successfully employed for several ternary and quaternary MAX phases, for instance by Liu *et al.* (2007); Naguib *et al.* (2014); Meshkian *et al.* (2017). Pressureless sintering can be preceded by mechanical alloying (MA). Nechiche *et al.* (2017) introduced Cu as an element into the Ti_3AlC_2 structure by MA in combination with pressureless sintering. Additionally, microwaves can be used as an alternative heat source. Ti_2AlN MAX phase grains were observed to grow in a preferred orientation upon microwave sintering, but the mechanism behind this is not fully understood (Liu *et al.*, 2015).

Reactive hot pressing and hot isostatic pressing have been reported numerous times for the Ti-Al-C system and are excellent techniques to synthesize high purity, dense Ti_2AlC and Ti_3AlC_2 on a lab-scale. The important process parameters are the chemistry of the starting powders and their stoichiometric ratio, sintering temperature (commonly in the 1200–1500°C range), dwell time (0.5–16 h), pressure (30–70 MPa) and, optionally, a heat treatment at lower temperature. As starting powder, elemental powders are the most obvious choice, but also binary compounds, such as TiC_x , Al_4C_3 and TiH_2 , are used (Zou *et al.*, 2006, 2007). The latter acts as Ti-source as it is more economical and less pyrophoric compared to fine pure Ti powder (Li *et al.*, 2013b). The hydride dehydrogenates in situ around 600°C. Al_4C_3 is reported as an effective Al and C source in several Ti-Al-C MAX phase synthesis reports. However, due to the hygroscopic nature of this carbide, Al_2O_3 is reported as a parasitic phase in the final product (Tzenov and Barsoum, 2000). The main limitations of HP and HIP are the rather slow processing cycles in combination with a limited amount of material per run which makes these techniques, especially HIP, rather costly. The speed of the process can be increased using SPS (also known as PDS or FAST) due to higher heating and cooling rates and short dwell times of only a few minutes. Moreover, the reported SPS synthesis temperatures are generally 50–200°C lower compared with hot pressing. For instance, Yang *et al.* (2009) reported the synthesis of dense Ti_3AlC_2 by combining mechanical alloying (MA) and SPS at 1050°C. It is unclear whether this difference with more conventional HP or HIP can be related to the nature of the process, enhanced diffusion due to the current flow, or whether it is just an artefact of the way the temperature is measured.

Formation and Dissociation Mechanisms

So far, a single generally valid formation mechanism has not been identified for the family of MAX phases. Nevertheless, some reports try to clarify the formation of specific MAX phases starting from elemental powders. Considering the reported reaction pathways for some 211 carbide structures, such as Ti_2AlC by Pietzka and Schuster (1994) and Low (2012), Ti_2SnC by Li *et al.* (2006), Cr_2AlC by Tian *et al.* (2007b) and Nb_2AlC by Hu *et al.* (2012), a similar sequence can be identified. After melting the A-element, M_xA_y -intermetallics are formed. These tend to evolve from an A-rich intermetallic phase towards a more M-containing compound. The next step differs for Ti and Nb compared to Cr. Ti and Nb intermetallics react with C resulting in a binary MC_x or at higher temperature in the formation of another complex ternary carbide, i.e., Ti_3AlC or $\text{Nb}_3\text{Al}_2\text{C}$. In the case of Cr-intermetallics, C directly reacts with the intermetallic forming the 211 structure (Tian *et al.*, 2007b):

For $\text{M} = \text{Ti}$ or Nb , the reported C-source in the MAX phase-forming reaction is commonly the binary or ternary carbide (Li *et al.*, 2006; Hu *et al.*, 2012; Low, 2012; Lapauw *et al.*, 2016a):

The formation reactions in these four systems give a first idea on how the M_2AX phases can be synthesized. However, a few remarks should be added to these straightforward reactions. First of all, regarding the X source, even for the systems presented above, MAX phase synthesis has been reported starting from alternative carbon sources in the starting powder, such as Cr_3C_2 or Al_4C_3 (Tzenov and Barsoum, 2000; Lin *et al.*, 2007), which will most likely modify the reaction path. If $\text{X} = \text{N}$, the starting powders are MN_x , or when $\text{A} = \text{Al}$, AlN has also been used by Procopio *et al.* (2000). Secondly, these reaction paths are based on interrupted sintering experiments and constitute a good approximation. However, they are still a simplification of the local reaction front where nucleation and growth take place. Additionally, the effect of impurities should not be underestimated. They can hinder the formation or destabilize certain MAX phases. Tzenov *et al.* (2000) reported that the presence of 1% of Fe or V impurities in Ti-Si-C starting powder causes noticeable Ti_3SiC_2 MAX phase dissociation and, hence, TiC_x formation. On the other hand, Nowotny (1972) already noted the importance of the presence of impurities and stated that: “minute amounts of other non-metal elements (N, O, H, etc.) are sometimes able to stabilize carbide structures, which either do not exist or cannot be prepared in the absence of these impurities.” Although not frequently reported upon, impurities likely play a very important role in the (non-) formation of MAX phases. Although not soluble in the MAX phase itself, the addition of Fe, Co or Ni assisted in the formation of

Ti_3SnC_2 , Zr_3SnC_2 and Hf_3SnC_2 MAX phases, whereas their 211 Ti_2SnC , Zr_2SnC and Hf_2SnC equivalents were formed in the undoped M-Sn-C mixtures (Lapauw *et al.*, 2017).

Most of the 312 and 413 MAX phases can be obtained by heat treating their corresponding 211 phase. In this regard, Lane *et al.* studied the transition in the Ti-Al-C system. They observed a change from a 211 to a 523 atomic stacking sequence by the outward diffusion of Al and rearrangement of the $\text{Ti}_{n+1}\text{C}_n$ blocks. This topotactic transformation is reported by Lane *et al.* (2012) as an intermediate step in the conversion towards Ti_3AlC_2 and eventually TiC_x . Finally, Ti_3SiC_2 is in this respect particular as no 211 structure exists. The in situ formation of this MAX phase structure by SHS of a Ti, SiC and C powder mixture was captured in an ultra-high-speed neutron diffraction study. Just before the MAX phase formation, a single NaCl-structured material was observed. This was postulated by Riley *et al.* (2002) to be TiC with Si in solid solution, out of which Ti_3SiC_2 can grow. A similar reaction principle was observed by Abdulkadhim *et al.* (2011) during magnetron sputtering of Ti, Al and C by direct formation of MAX phases by Al intercalation into TiC_x ($0.4 \leq x \leq 1$).

The opposite reaction occurs for most MAX phases when heated above a certain temperature. As indicated by reaction (3), the MAX phases dissociate and transform into MC_x where the A-element melts or sublimates. The remaining M_{n+1}X_n structure relaxes and de-twinning of these slabs form $\text{TiC}_{0.67}$ (Emmerlich *et al.*, 2007). The dissociation reaction is limited by the outward diffusion of the A element (Pang *et al.*, 2010). Apart from thermal degradation, the presence of impurities can lower the stability of certain MAX phases and cause the presence of MX compounds (Tzenov *et al.*, 2000).

Attractive Properties of the MAX Phases

The systematic study of MAX phase properties started when Barsoum and El-Raghy (1996) revealed the fascinating properties of Ti_3SiC_2 . The extraordinary combination of a high fracture toughness, excellent oxidation and corrosion resistance, good high temperature stability and machinability formed the driving force in MAX phase research. A short overview of these five properties is given below, starting with what was labeled a “Mechanical Wonder” in Barsoum (2000).

Fracture Toughness and Damage Tolerance

Ceramic materials are generally associated with a brittle mechanical behavior. They lack energy absorbing mechanisms, such as dislocation motion in metals. Therefore, most ceramics have a low resistance to crack propagation and correspondingly have a modest fracture toughness (K_{IC}). In most engineering applications, however, this property is a prerequisite for the design of a structural component, hence, limiting the use of ceramic materials. One of the unique features of MAX phase materials is the presence of additional energy absorbing mechanisms, which can make them multiple times more tough than their corresponding binary carbides. The damage tolerant mechanisms are related to their nano-layered nature, but cannot be explained solely by this structure. As Barsoum (2013) pointed out, several other laminated materials exist that have a relatively low fracture toughness, such as graphite and MoS_2 . In the MAX phases, additional toughening mechanisms are present, including dislocation

Fig. 6 Toughening deformation mechanisms in MAX phases: (a) kinking, (b) delamination, and (c) shearing of individual Nb_4AlC_3 platelets that allow crack bridging. Additionally, Nb_4AlC_3 undergoes (d) intergranular cracking.

multiplication and motion in the basal plane, crack deflection and bridging, delamination, kink boundaries and plastically deformable bridge ligaments. An illustration of a heavily deformed bridge ligament is shown in Fig. 6(a).

Of particular interest are the different ways on how to make optimal use of these toughening mechanisms. Grain alignment was found to be a very useful method to further improve fracture toughness. One way to realize this is by slip casting a MAX phase powder suspension in a strong magnetic field (12 T) and subsequently densifying the green compact by SPS. This method was successfully employed for Nb₄AlC₃, Ti₃SiC₂ and Ti₃AlC₂ (Hu *et al.*, 2011a,b,d; Zhang *et al.*, 2015a). The MAX phases are susceptible to a strong magnetic field due to their anisotropic unit cell. The *c*-axis tends to align parallel to the magnetic field. A record K_{IC} value of $17.9 \pm 5.2 \text{ MPa m}^{1/2}$ was measured on highly textured Nb₄AlC₃ loaded perpendicular to the basal plane. The concomitant flexural strength was 1.2 GPa, which indicates that grain alignment caused an overall improved mechanical behavior. The fracture toughness recorded in the perpendicular direction was $11.5 \pm 1.4 \text{ MPa m}^{1/2}$, which is still significantly higher than $7.1 \text{ MPa m}^{1/2}$ for Nb₄AlC₃ with randomly oriented grains. This improved mechanical behavior was explained by the additional crack deflection induced by the stacked platelet-like microstructure. This results in a zigzag pattern caused by crack deflection. It should be mentioned that the value of $17.9 \text{ MPa m}^{1/2}$ was measured on a material with about 15 vol% of Al₂O₃. As reported in Hu *et al.* (2011c), these oxide particles also act as crack deflectors and improve the fracture toughness. They repeated the grain alignment procedure followed by SPS for Nb₄AlC₃ material with 3 vol% Al₂O₃, which resulted in a K_{IC} of $14.1 \text{ MPa m}^{1/2}$ and $9.3 \text{ MPa m}^{1/2}$ parallel and perpendicular to the *c*-axis, respectively. These lower values clearly illustrate that the secondary oxide particles can enhance the fracture toughness. Texturing of MAX phases is also possible by plastic deformation of fully dense bulk material at elevated temperature, as demonstrated in Lapauw *et al.* (2016e) by spark plasma deformation of hot pressed Ti₃SiC₂, Ti₃AlC₂/Ti₂AlC, Nb₄AlC₃ and (Nb_{0.85},Zr_{0.15})₄AlC₃ or by SPS of milled pressureless sintered Cr₂AlC, as shown by Duan *et al.* (2015).

Oxidation Resistance and Crack Healing

A second attractive aspect of some MAX phases is their excellent oxidation resistance. The stability of the material in oxidative environments relies on the formation of a well-adherent protective oxide layer that shields the underlying material. MAX phase compounds known for their good oxidation resistance (i.e., stable above 1000°C) are Ti₃SiC₂, Ti₂AlC, Ti₃AlC₂ and Cr₂AlC. Ti₃SiC₂ forms a duplex oxide layer with an outer rutile (TiO₂) layer followed by a mixture of TiO₂ and silica (SiO₂), which shows a stable oxidation behavior up to about 1100°C (Barsoum *et al.*, 1997; Sun *et al.*, 2001). The three other compounds mainly rely on the formation of a stable α -Al₂O₃ layer. A comprehensive review of their oxidation behavior is given by Tallman *et al.* (2013), where Ti₂AlC is reported as the most oxidation-resistant MAX phase. The oxide layer is well-adherent up to 1350°C due to the excellent match in coefficient of thermal expansion (CTE) between alumina and Ti₂AlC. Thin Al₂O₃ scales of 15 μm have been reported after 8000 thermal cycles by Sundberg *et al.* (2004). The oxidation process of Ti₃AlC₂ is similar, but this MAX phase has a lower amount of Al that makes the formation of a continuous α -Al₂O₃ layer less probable and increases the oxidation rate. Nevertheless, a stable oxidation behavior was observed up to 1300°C by Wang and Zhou (2003). Cr₂AlC has the same Al-content as Ti₂AlC and a slower oxidation rate than Ti₂AlC below 1200°C. During oxidation however, this MAX phase forms a Cr₇C₃ layer underneath the Al₂O₃ layer with poor oxidation resistance (Lee *et al.*, 2007). This unique feature, i.e., the fact that Cr₂AlC is the only MAX phase forming a binary carbide layer underneath, makes Cr₂AlC prone to oxidation in case of damage of the alumina layer. Moreover, the thermal expansion of Cr₂AlC is significantly higher than for alumina. These facts limit its applicability (Tallman *et al.*, 2013). Doping the MAX phases or creating solid solutions was found to be beneficial for improving the oxidation resistance of MAX phases, such as Ti₃(Al,Si)C by Nb, Ti₃SiC₂ by Al, Nb₂AlC by Ti, and Nb₄AlC₃ by Ti addition reported, respectively, by Zheng *et al.* (2011), Zhang *et al.* (2004), Salama *et al.* (2003) and Gu *et al.* (2016). Although not a MAX phase, an improved oxidation resistance of Zr₂(AlSi)₄C₅ was reported by Lu *et al.* (2011) by replacing 20 at% Zr with Ti.

The study of the oxidation behavior of MAX phases in the Ti-Al-C system has revealed their ability to “heal” cracks. This healing consists of a heat treatment of Ti₂AlC or Ti₃AlC₂ in oxidative environment that fills the crack with TiO₂ and Al₂O₃ oxidation products, thereby (partially) restoring the strength of the material (Song *et al.*, 2008; Yang *et al.*, 2011). A similar behavior was observed for Cr₂AlC by Li *et al.* (2013a). Farle *et al.* (2015) carried out a study aimed at identifying other MAX phases suitable for this kind of self-healing behavior. They listed a set of thermodynamic and mechanical requirements based on which they selected some potential candidate self-healing MAX phases, including V₂AlC, Ti₃SiC₂ and Zr₂AlC. Li *et al.* (2016) and Li *et al.* (2017) demonstrated the healing of thermal shock-induced cracks in Ti₂SnC. They showed a restored strength after treatment in air where the large cracks were filled with TiO₂ and SnO₂ and the smaller cracks with metallic Sn. Crack healing is an added value for all materials subject to mechanical load. The Ti₂SnC example shows this behavior can also be observed for A-elements different from the most-commonly studied Al and Si.

Corrosion Resistance in Liquid Metals

MAX phase research for select applications in Gen-IV lead-cooled fast reactors (LFRs) demands the compatibility of the candidate structural/functional MAX phase-based materials with the heavy liquid metal (HLM) primary coolant, such as lead (Pb) and lead-bismuth eutectic (LBE). Under service conditions where conventional stainless steels suffer heavily from dissolution corrosion

Table 2 Overview of liquid Pb and LBE exposure studies of MAX phases in literature

Fig. 7 Materials exposed to oxygen-poor, static LBE at 500°C for 1000 h: (a) $(\text{Nb}_{0.85}\text{Zr}_{0.15})_4\text{AlC}_3$ MAX phase solid solution, (b) 316L SA (solution annealed) stainless steel. Materials exposed to oxygen-poor, fast-flowing LBE at 500°C for 1000 h: (c) $(\text{Nb}_{0.85}\text{Zr}_{0.15})_4\text{AlC}_3$ MAX phase solid solution, (d) 316L SA stainless steel.

(Lambrinou *et al.*, 2017), e.g., high temperatures ($>450^\circ\text{C}$) and low HLM oxygen concentration ($C_{\text{O}} < 10^{-8}$ mass%), most MAX phases remain inert in contact with liquid LBE.

The liquid metal corrosion (LMC) resistance of the MAX phases is an appealing property that made them stand out as candidate materials for Gen-IV LFRs. The liquid Pb and LBE interaction experiments that have been reported in literature are summarized in [Table 2](#). Commercially available MAX phase ceramics, i.e., Maxthal® 312 (Ti_3SiC_2 and TiC) and Maxthal® 211 (Ti_2AlC , Ti_3AlC_2 and TiAl), were exposed to liquid Pb and LBE at reactor-relevant temperature ranges in order to assess their compatibility with these HLM coolants. No major corrosion effects were observed that could jeopardize the structural integrity of the MAX phase component. The most severe interaction with the HLM was the dissolution of the remaining TiAl phase in the Ti_2AlC ceramic, which resulted in LBE ingress into the material bulk (Heinzel *et al.*, 2016). Thin rutile TiO_2 formation was observed on Ti_3SiC_2 . Lapauw *et al.* (2019) reported on the stability of 11 MAX phase ceramics in oxygen-poor ($C_{\text{O}} \leq 2.2 \times 10^{-10}$ mass%) liquid LBE at 500°C for 1000–3500 h. In static LBE exposure tests, Maxthal® 312, Maxthal® 211, $(\text{Ti,Nb})_2\text{AlC}$, Nb_2AlC , Nb_4AlC_3 and $(\text{Nb}_{0.85}\text{Zr}_{0.15})_4\text{AlC}_3$ did not show any interaction with the HLM. It was concluded that these MAX phase ceramics were either intrinsically resistant to LBE attack or were passivated by a nanometric Al_2O_3 or SiO_2 oxide scale, as it is known that both Al_2O_3 and SiO_2 are stable at $C_{\text{O}} < 10^{-15}$ mass% at 500°C in liquid LBE (Schroer and Konys, 2007).

LBE interaction was observed in Ti_2SnC , where the competing Sn phase was dissolved by LBE that was found at the grain boundaries (Lapauw *et al.*, 2019). The susceptibility of competing phases that are rich in the A-element was also shown by Heinzel *et al.* (2016), who reported the dissolution of the TiAl phase present in Ti_2AlC . These findings indicate the importance of phase purity on the LMC resistance of MAX phases. The most severe interaction was observed in Zr-rich MAX phases (Zr_2AlC , Zr_3AlC_2 , $(\text{Zr}_{0.8}\text{Ti}_{0.2})_{n+1}\text{AlC}_n$) exposed to static liquid LBE (Lapauw *et al.*, 2019). Local LBE interaction was found only with the MAX phase grains, while the surface integrity of the ceramic was maintained. Attacked Zr-rich MAX phase grains were in-situ transformed into $\text{Zr}(\text{Ti})_{n+1}(\text{Al,Bi,Pb})\text{C}_n$ MAX phase solid solutions (Tunca *et al.*, 2020). The LBE dissolution attack of the intermetallic phases in the $(\text{Zr}_{0.8}\text{Ti}_{0.2})_{n+1}\text{AlC}_n$ ceramic was also observed. Lapauw *et al.* (2019) also reported that tests conducted for 1000 h at 500°C in oxygen-poor ($C_{\text{O}} \approx 5 \times 10^{-9}$ mass%), fast-flowing ($v \approx 8 \text{ m s}^{-1}$) liquid LBE resulted in 3–4 μm thick Nb_2O_5 -based oxide scale formation on $(\text{Nb}_{0.85}\text{Zr}_{0.15})_4\text{AlC}_3$. While both Zr_2AlC and Zr_3AlC_2 formed porous ZrO_2 layers, oxidation was milder in Zr_2AlC . Under fast-flowing LBE conditions, no signs of erosion or erosion/corrosion were observed in the MAX phase ceramics. Solution-annealed 316L stainless steels tested as reference structural material in the same experiment showed erosion damage (Fig. 7).

Stability at Elevated Temperature

Transition metal carbides are known as refractory carbides, due to their excellent high temperature strength. The MAX phases are reported to have a good stability at elevated temperature. Primarily, this thermal stability can be interpreted in terms of phase

Fig. 8 Temperature dependence of the normalized Young's modulus and mechanical damping for $(\text{Nb}_{0.85}\text{M}_{0.15})_4\text{AlC}_3$ with $\text{M} = \text{Ti}, \text{Zr}, \text{Hf}$ compared to unalloyed Nb_4AlC_3 . stability. As mentioned in Section “Formation and Dissociation Mechanisms,” the MAX phases dissociate at elevated temperatures and the exact dissociation temperature can vary roughly between 1000 and 1700°C, depending on the specific MAX phase and the environmental conditions. An overview of the different parameters controlling the decomposition and degradation of Ti-based MAX phases was published by Low (2019). The thermal decomposition of Ta_4AlC_3 is addressed in Griseri *et al.* (2019).

Another point of interest is the response of the MAX phases to mechanical loads at high temperature. The knowledge of this mechanical behavior is mainly based on experiments with Ti_3SiC_2 , complemented with some reports on Ti_3GeC_2 and Al-containing phases. A detailed overview is provided by Barsoum (2013). In general, the MAX phases have a brittle-to-plastic transition temperature (BPTT). Below the BPTT, their mechanical response is almost temperature-independent and they fail in a brittle way. Above the BPTT, the MAX phases can be plastically deformed and the plastic behavior becomes more pronounced at higher temperature as well as lower stress (σ) and strain rate ($\dot{\epsilon}$) (Barsoum *et al.*, 2001; Radovic *et al.*, 2002; Sun *et al.*, 2006). The activation of additional dislocation slip systems above the BPTT can be ruled out as explanation for the observed behavior, as the reported fracture toughness above the BPTT drops significantly (Wan *et al.*, 2008). The mechanism that is most likely responsible for the observed behavior is delamination and/or grain boundary decohesion (Barsoum, 2013). The temperature where softening of the grain boundaries and the brittle-to-plastic transition occurs can be measured by evaluating the stiffness as a function of

temperature. A drastic decrease in E-modulus indicates the transition towards the plastic regime (Radovic *et al.*, 2002). This transition also determines the temperature at which MAX phase components lose their load-bearing capacity and is, therefore, of interest when envisaging structural applications at elevated temperature. The ternary MAX phase that has been reported to have the best high temperature stability is Nb₄AlC₃. The evolution of the Young's modulus as a function of temperature has been reported by Hu *et al.* (2008), comparing Nb₄AlC₃ to the lower-order Nb₂AlC and Ta_{n+1}AlC_n phases. Nb₄AlC₃ clearly outpaced the other MAX phases, a fact that is also reflected in the mechanical damping. A linear decrease in stiffness was maintained until around 1400°C. Alloying Nb₄AlC₃ with Zr or Hf even further enhances the high-temperature stability (Lapauw *et al.*, 2016d, 2018a) Fig. 8.

Machinability

An important technological attribute regarding the production and shaping of components is the machinability of MAX phase compounds. They can be machined using conventional high-speed tool steel and hardmetal tools and, therefore, shaping of the MAX phases can be done using conventional machining processes such as milling, turning and drilling. A crucial prerequisite for machining is high phase purity, since parasitic carbide or oxide phases are detrimental to the tools. Some examples of MAX phase components are presented in Fig. 9. This shape flexibility is definitely one of the MAX phase assets that makes these ceramics stand out as compared to binary and other ternary transition metal carbides. The machinability is often compared to that of graphite. Barsoum *et al.* (2001) use the analogy with ice: “M_{n+1}AX_n compounds do not machine as one would scoop ice cream (as in metals), but rather as one would shave ice, i.e., by breaking off tiny microscopic flakes.” Since the MAX phases are good electrical conductors, they can also be machined using electrical discharge machining (EDM). This technique is less sensitive to the presence of competing, conductive phases, e.g., binary carbides, and still allows a high degree of shape flexibility.

Summary

This survey aimed at providing a short introduction to the MAX phases, of which the nano-layered structure leads to unusual combinations of properties. One of the most intriguing points is that some combinations of M, A and X elements are stable in the MAX phase structure, whereas other chemically similar M, A and X combinations do not form a MAX phase compound. Although one would expect a close crystallographic relation with the corresponding binary carbides/nitrides, the absence of a “Hägg-ian” rule similar to that holding for the transition metal carbides/nitrides opens up the possibility to still discover new ternary and quaternary or even multi-element MAX phases with similar or even improved properties. Despite the tremendous amount of newly discovered MAX phases, like o-MAX, i-MAX, HE-MAX, and double solid solution MAX phases, there are very few commercial MAX phase powder sources available at present and limited to the Ti₃SiC₂, Ti₂AlC, Ti₃AlC₂, V₂AlC and Nb₂AlC compositions. Bulk MAX phase ceramics, as far as we know, are not available on the market at present. Moreover, no high phase purity has been reported yet for ordered o-MAX or i-MAX ceramics, and their intrinsic material properties are still unknown. Despite the extremely interesting properties, such as damage tolerance, crack healing, oxidation resistance, relatively high temperature stability, liquid metal corrosion resistance, irradiation tolerance and machinability of some MAX phase compositions, most of the research on the MAX phases nowadays focuses on MXene synthesis, i.e., 2D transition metal carbides or nitrides synthesized by etching the A-element out of the MAX phase.

Introduction

Like carbon, boron forms strong covalent bonds with its three valence electrons. But being electron deficient, it cannot form 3D networks with two-center covalent bonding alone (Mori, 2008). Boron is a metalloid, so although its bonding electrons favor metallic behavior, they are strongly localized and insulating states emerge (Oganov *et al.*, 2009; Zhai *et al.*, 2014). Boron tends to form clusters in which B₁₂ icosahedra or cubo-octahedra are common structural units (Wiberg *et al.*, 2001; Greenwood and Earnshaw, 1997; Gogotsi and Andrievski, 1999; Higashi, 2000). Within the B-clusters, the valence electron density is high, so boron-rich solids feature strong covalent bonding and correspondingly high melting point, high hardness, low compressibility, yet light weight and low coefficient of thermal expansion. These properties make X-borides good candidates for use in applications involving extreme conditions where other materials fail, including: abrasives; cutting tools; lightweight armor; fiber reinforcement; neutron shielding; nuclear reactor control rods; sand-blaster nozzles; turbines blades; thermal protection systems (TPS) for rockets; electron emitting cathodes for electron microscopy; thermocouples; thermoelectrics; and many other amazing applications (Nabhani, 2001; Orton and Scuderi, 1998; Monteverde and Savino, 2012).

Boron has high affinity for transition- and rare-earth metals, which form many interesting borides. These include metallic B (Häussermann *et al.*, 2003); binary compounds: B₄C, ZrB₂, HfB₂, MgB₂, TiB₂, AlB₂, ReB₂, OsB_{1.1}, AuB₂, Os₂B₃, OsB₂, RhB₂, RuB₂, PtB₂, IrB₂, CrB₄, MnB₄, WB₄, LaB₆, SiB₆, CeB₆, PrB₆, NbB₆, ZrB₁₂, HfB₁₂, AlB₁₂, YB₁₂, YB₆₆ (Thevenot and Roy, 1991; Sonber and Suri, 2011; Wuchina *et al.*, 2004; Buzea and Yamashita, 2001; Basu *et al.*, 2006; Xiao-Lin *et al.*, 2006; Liang and Zhang, 2007; Stuparević and Živković, 2004; Hebbache *et al.*, 2006; Gou *et al.*, 2006; Wang *et al.*, 2012; Gou *et al.*, 2012); ternary compounds: AlMgB₁₄, ErAlB₁₄, AlCrB₁₄ (Muthu *et al.*, 2008; Liu *et al.*, 2013; Roberts *et al.*, 2009); and many other B compounds (Gu *et al.*, 2008; Weinberger *et al.*, 2009; Rau and Latini, 2009; Ivanovskii, 2012; Lazar *et al.*, 2009). Metal atoms provide additional electrons that stabilize structures, resulting in new properties. When M is a rare earth, adding even small amounts of C, N, or Si leads to complex ternaries, like MB_{15.5}CN, MB₂₂C₂N, MB_{28.5}C₄, MB₁₈Si₅. Although most borides are *p*-type conductors or semiconductors (Mori and Nishimura, 2006), homologous M-B-C(N) borides are *n*-type conductors (Mori, 2008). Very few borides have a band gap above 2 eV (Peditakis *et al.*, 2010; Hubert *et al.*, 1998), so most are darkly colored or opaque and unsuitable for optical applications.

Borides are attracting great interest (Kaner *et al.*, 2009; Chung *et al.*, 2008; Chen *et al.*, 2006; Aydin and Simsek, 2009) due to the demand for high-performance materials (Cutler, 1991). ReB₂, OsB₂, IrB₂, RuB₂, CrB₄, WB₄, IrB₂, IrB_{1.1}, IrB_{1.35} and related borides with remarkable properties were reported by: Xie *et al.* (2015a), Suh *et al.* (2007), Živković and Stuparević (2005) and Deligoz *et al.* (2012). ReB₂, OsB₂, and IrB_x received special attention for their extreme stiffness and incompressibility, which results from the high B-B and M-B bond covalency (Xie, 2014; Levine *et al.*, 2008; La Placa and Post, 1962). ReB₂-type hexagonal OsB₂ that exhibits ultra-high hardness (31 ± 9 GPa) and Young's modulus (574 ± 112 GPa), a ReB₂-type IrB₂ and IrB monophase were reported by: Xie *et al.* (2015b, 2014a,b), Orlovskaya *et al.* (2018, 2014) and Xie *et al.* (2015c, 2016a,b). Nanoindentation of OsB₂ revealed a reversible "pop-in" event during loading and unloading, which evidences a previously unknown high-pressure AlB₂-type OsB₂ phase. Upon heating, *hex*-OsB₂ exhibits a *negative* thermo-chemical expansion in the crystallographic *a*-direction (Xie *et al.*, 2014a,b). This points to a super-hard, stiff OsB₂ phase with unexpected thermal and mechanical behavior (Levine *et al.*, 2009; Knappschneider *et al.*, 2013). Yet, the properties of recently synthesized IrB₂, IrB (Xie *et al.*, 2016a, 2015c; Orlovskaya *et al.*, 2014), and many other binary and ternary compounds remain completely unexplored (Kempter and Fries, 1961). Here we report on the processing, structure, and properties of ZrB₂, HfB₂, OsB₂ and IrB₂ diboride ceramics.

Processing of ZrB₂, HfB₂, OsB₂, and IrB₂ Ceramics

All four diboride compounds reported are hard to synthesize and require high temperature sintering under pressure. ZrB₂ and HfB₂ ceramics can be sintered using commercially available powders; however, OsB₂ and IrB₂ powders are not available on the market and have to be synthesized using available techniques. One of the techniques reported for the synthesis of OsB₂ and IrB₂ powder composites is high energy ball milling or mechanochemistry (Ivanov and Suryanarayana, 2000). A special milling process is usually employed using mills where high axial and shear forces are produced by frequent ball impact events, which fracture the particles followed by solid state diffusion reactions leading to the formation of the target compounds. Shear stress and strain play a major role in the mechanochemical synthesis as the shear strength of many compounds is much lower in comparison with their

Fig. 1 Sintering regimes used for the densification of ZrB₂, HfB₂, and OsB₂ powders. Temperature, pressure, and shrinkage data as a function of time during spark plasma sintering are presented. (A) ZrB₂; (B) HfB₂; (C) OsB₂. Reproduced from Xie, Z., Lugovy, M., Orlovskaya, N., *et al.*, 2015b. Hexagonal OsB₂: Sintering, microstructure and mechanical properties *Journal of Alloys and Compounds* 634, 168–178.

compressive uniaxial strength. Therefore, if shear deformation is present, the solid-state synthesis could be favored over those techniques where only axial or hydrostatic pressure are acting alone. The level of applied axial and shear stresses present during mechanochemical synthesis was estimated by Xie *et al.* (2016a). These stresses result in plastic deformation of nanoparticles at the atomic level, which is very important to facilitate solid state chemical reactions using mechanochemistry.

Table 1 Microstructure parameters for OsB₂ after SPS

Composition	Grain size, μm	Porosity, %
ZrB ₂	18.52 ± 10.45	3
HfB ₂	2.75 ± 1.28	8.87
OsB ₂	0.56 ± 0.26	26.9

Mechanochemical high energy ball milling was used to synthesize ReB₂-type hexagonal OsB₂ and IrB₂ compounds (Orlovskaya *et al.*, 2018, 2014). Mechanochemical synthesis involving milling of Os and Ir metal powders with elemental B powders for extended period of time using WC media and balls allowed the production of the hexagonal OsB₂ and IrB₂ metastable high pressure phases for the first time (Xie *et al.*, 2014b, 2016a). Therefore, the mechanochemical approach was successfully used to synthesize previously unknown metastable OsB₂ and IrB₂ phases, which cannot be easily processed by other available means.

Spark Plasma Sintering has become a very popular sintering technique, where electric current activated sintering is used to sinter hard to densify materials, such as borides (Munir *et al.*, 2006). The SPS technique is used to densify powders under simultaneous application of an electric current and pressure. During this process, powders are packed in a graphite die and heating is conducted by passing a pulsed DC current through the die and, if sufficiently electrically conductive, the powders. This process coincides with the application of uniaxial pressure to the powders using graphite punches. Both high heating rates, electric currents, and application of pressure play a significant role in fast densification of the ceramics by SPS (Munir *et al.*, 2006; Dudina *et al.*, 2019). The advantages of SPS compared to pressureless sintering or hot pressing include shorter dwell time, lower sintering temperature and improved mechanical and physical properties of materials consolidated using the SPS technique.

SPS has been used to densify boride ceramics, such as ZrB₂ and HfB₂. The typical sintering conditions used for densifying ZrB₂ included heating rate of 100–150°C min⁻¹ and pressure of 15–100 MPa with a dwell of 5–35 min at temperatures between 1900 and 2100°C. In addition to the conventional SPS technique for processing of boride ceramics, the recently developed Flash Spark Plasma Sintering technique was used to densify borides. Grasso *et al.* (2014) achieved densification of pure ZrB₂ to above 95% relative density using a very rapid heating rate (4000°C min⁻¹), very short processing time (35 s) and temperature range 2100–2200°C.

The commercially available ZrB₂ and HfB₂ powders were sintered using SPS (SPS machine FCT HPD 25; FCT Systeme GmbH, Rauenstein, Germany). The sintering of both compounds was performed under identical processing conditions of 2100°C, heating rate of 100°C min⁻¹, 35 min dwell time and 15 MPa applied pressure (Fig. 1(A)). From the shrinkage plots, it can be seen that the densification behavior of ZrB₂ and HfB₂ are very different. Originally, upon heating from room temperature the equipment exhibits a small expansion, but when the pressure is increased from the initial minimum pressure, both materials shrink in a similar way. However, while the 15 MPa max pressure and 2100°C max temperature are reached at the same time, the shrinkage of the two powders behave differently. ZrB₂ experiences a sharp densification, with the shrinkage decreasing dramatically once the temperature and pressure reach their maximum (Fig. 1(A)). During the dwell time of 35 min there is very little further densification, which is indicative that ZrB₂ is fully dense or contains very little porosity. In fact, the densification of the ceramics suggests that during the dwell time ZrB₂ might experience significant grain growth behavior and that the dwell time during sintering of ZrB₂ at 2100°C might need to be shorter than 35 min to produce materials with fine grains. Unlike ZrB₂, HfB₂ did not densify completely by the time the temperature and pressure reached their maximums at 2100°C and 15 MPa, respectively (Fig. 1(B)). HfB₂ continued shrinking throughout the 35 min of the dwell time and, in fact, never reached the complete densification stage. Therefore, based on its shrinkage behavior, it was expected that a certain amount of porosity could be found and smaller grain size would be retained at the end of SPS processing of HfB₂.

The mechanochemically synthesized hexagonal OsB₂ powder was sintered using Spark Plasma Sintering (SPS) (SPS 25–10, Thermal Technologies, CA). The sintering of the powder packed in the graphite die was performed at 1500°C, 50 MPa for 5 min with heating and loading rates of 47°C min⁻¹ and 10 MPa min⁻¹ respectively. The sintering behavior of OsB₂ in terms of both temperature and pressure, along with a shrinkage plot, are shown in Fig. 1(C). As can be seen, at the beginning of the temperature increase, a small expansion of the material is observed up to 685°C; however when temperature exceeded 685°C, the slow shrinkage of OsB₂ became evident. At 1000°C a uniaxial pressure was applied, reaching 50 MPa at 1220°C, which resulted in a significant densification of the powder. Upon further temperature increase, a small shrinkage was further observed in the 1425–1500°C temperature range, followed by slow densification during a 5 min isothermal dwell at 1500°C. As the shrinkage did not stop during the isothermal dwell, it was apparent that the material did not fully densify and porosity was expected. Upon cooling, the shrinkage of the material continued, mainly due to temperature decrease. Therefore, by using the chosen sintering conditions, an incomplete densification of h-OsB₂ occurred and rather porous bulk material was produced (Xie *et al.*, 2015b). The porosity, phase composition and grain size of OsB₂ after SPS is given in Table 1. While ZrB₂, HfB₂, and OsB₂ were densified using SPS, to date IrB₂ and mixture of other Ir-B phases have not been sintered; their sintering behavior will be investigated in future work.

Table 2 The lattice parameters of all of the hexagonal ZrB₂, HfB₂, OsB₂ and IrB₂ phases

Composition	Space Group	Lattice parameters, Å		
		<i>a</i>	<i>c</i>	<i>a/c</i>
ZrB ₂	<i>P6₃/mmm</i>	3.17	3.53	0.898
HfB ₂	<i>P6₃/mmm</i>	3.14	3.48	0.902
OsB ₂	<i>P6₃/mmc</i>	2.916	7.376	0.395
IrB ₂	<i>P6₃/mmc</i>	2.926	7.543	0.388

Structure of ZrB₂, HfB₂, OsB₂, and IrB₂ Ceramics

Crystal Structure

The characterization of ZrB₂, HfB₂, OsB₂ and IrB₂ borides was performed to determine their crystal structure and phase composition using X-ray diffraction, and microstructure using X-ray diffraction as well as SEM coupled with EBSD and TEM coupled with SAED. Room temperature X-ray diffraction was used to determine the crystal symmetry, unit cell, and the lattice parameters of hexagonal ZrB₂, HfB₂, OsB₂ and IrB₂ diboride ceramics. Selected measurements were also performed at high temperature under inert, oxidizing and reducing atmospheres (Ar, N₂, air, O₂ or vacuum) by XRD to determine how environmental conditions affect the stability of the ZrB₂, OsB₂ and IrB₂ diboride ceramics (Xie *et al.*, 2015a, 2016b). It was determined that ZrB₂, HfB₂, OsB₂ and IrB₂ ceramics all have the hexagonal symmetry. However, it was determined that ZrB₂ and HfB₂ crystallize in the *P6₃/mmm* space group (Lawson *et al.*, 2011), while OsB₂ and IrB₂ crystallize in the *P6₃/mmc* space group (Xie *et al.*, 2014b). It was reported that at room temperature ZrB₂ and HfB₂ have lattice parameters, respectively, of *a* = 3.17 Å and *c* = 3.53 Å; and *a* = 3.14 Å and *c* = 3.48 Å, while those for OsB₂ and IrB₂ are *a* = 2.916 Å and *c* = 7.376 Å; and *a* = 2.926 Å and *c* = 7.543 Å, respectively. The *a/c* ratio was rather large for ZrB₂ and HfB₂ ceramics; however both OsB₂ and IrB₂ compounds had significantly lower *a/c* ratio (Table 2). It was also determined that ZrB₂ did not contain any detectable secondary phases, HfB₂ and OsB₂ contained small amounts of related secondary phases, while newly discovered IrB₂ was a secondary phase itself in the mixture of related secondary phases of IrB_{1.35} and IrB. The phase composition of ZrB₂, HfB₂, OsB₂, and IrB₂ compounds is shown in Table 3.

The X-ray diffraction patterns of hexagonal *P6₃/mmm* space group ZrB₂ and HfB₂ ceramics sintered at 2100°C using Spark Plasma Sintering are shown in Fig. 2. As can be seen from Fig. 2, ZrB₂ is phase pure, while HfB₂ after sintering contains a small amount of the monoboride HfB with cubic space group and lattice parameter *a* = 4.63 Å and monoclinic HfO₂ phase with *P2₁/a* space group and lattice parameters *a* = 5.29 Å; *b* = 5.16 Å; *c* = 5.14 Å. Unlike ZrB₂ and HfB₂, OsB₂ was crystallized into hexagonal *P6₃/mmc* space group lattice after high energy ball milling and a schematic presentation of this metastable ReB₂-type OsB₂ crystal structure is shown in Fig. 3. This structure consists of alternating layers of hexagonally arranged osmium and boron. Boron forms infinite sheets consisting of 6-membered rings in a chair configuration (Xie *et al.*, 2014b). This hexagonal ReB₂-type OsB₂ structure was predicted to have high bulk and shear moduli, *i.e.*, an improved hardness, due to the shortened Os-Os bonds as compared to the thermodynamically stable orthorhombic OsB₂ (Orlovskaya *et al.*, 2018).

An X-ray diffraction pattern of IrB₂ and related phases of Ir-B ceramics is shown in Fig. 4. A mixture of three Ir-B phases was reported, where IrB₂ diboride and IrB monoboride were reported to exist as minor phases in the batch with the IrB_{1.35} structure (Xie *et al.*, 2016a), similar to the reported hexagonal OsB₂ (Xie *et al.*, 2014b). A previously non-reported ReB₂-type IrB₂ structure as well as a new orthorhombic iridium monoboride (IrB) structure have been discovered in this work for the first time. The lattice parameters of all hexagonal ZrB₂, HfB₂, OsB₂ and IrB₂ phases are presented in Table 2.

Microstructure

The microstructures of ZrB₂ and HfB₂ ceramics are shown in Fig. 5. While the same sintering conditions (2100°C, 15 MPa, 35 min dwell time) were used for processing of both ceramics, the sintering behavior of these two materials was very different, resulting in different mechanisms of grain growth, porosity, and even formation of texture during densification. The band contrast images of the microstructure revealed that ZrB₂ was well sintered, contained low porosity (<3%) and had an average grain size of 18.52 μm ± 10.45 μm. Apparently, significant solid state diffusion had occurred during sintering of ZrB₂ that was responsible for grain growth and complete densification. Texture also resulted as the sintering occurred under a uniaxial stress. The pole figures for ZrB₂ (Fig. 5(E)) show the presence of texture, thus making ZrB₂ ceramics slightly anisotropic after processing by SPS, where the basal (0001) planes were oriented perpendicular to the direction of the applied stress. Therefore, ZrB₂ exhibited some degree of anisotropy after densification.

Unlike ZrB₂, HfB₂ exhibited very different sintering behavior. While ZrB₂ was much more easy to densify and achieve full density, which was accompanied by significant grain growth, HfB₂ densified very differently under the same (2100°C, 15 MPa, and 35 min dwell time) sintering conditions as ZrB₂. It was not possible to fully sinter HfB₂ and it had a significant amount of porosity (up to 9%) and its average grain size was 2.75 μm ± 1.28 μm after densification. From such a difference, it might be concluded that solid state diffusion is much more limited in HfB₂, leading to significant residual porosity and much smaller average grain size, compared with ZrB₂. Also, no preferred crystallographic orientation was found to form after sintering, such that effectively

Table 3 The phase composition of processed ZrB₂, HfB₂, OsB₂, and IrB₂ compounds

Compound	Phases	Weight %
ZrB ₂	ReB ₂ -type ZrB ₂	100
HfB ₂	ReB ₂ -type HfB ₂	96.58
	HfB	2.32
	HfO ₂	1.1

sintered HfB₂ was fully isotropic, despite the applied pressure used during sintering by SPS (**Fig. 5(F)**). The pole figures of HfB₂ indicated the absence of texture, thus showing this ceramic to be fully isotropic.

ZrB₂ and HfB₂ ceramics are both well-known and well characterized materials, and their powders are available from commercial vendors. It is impossible to source OsB₂ from commercial companies. Therefore, the powder of this compound was synthesized using mechanochemistry (Ivanov and Suryanarayana, 2000). As mechanochemistry employs high normal and deviatoric stresses accompanied by elevated temperatures during milling of Os and B powders, the process leads to the formation of metastable ReB₂-type hexagonal OsB₂, which was reported by Xie *et al.* (2014b). It was also possible to retain its hexagonal structure after densification at 1500°C by SPS. After such high temperature sintering, 80% of OsB₂ was retained as the hexagonal *P63/mmc* space group structure, while 20% was converted into the thermodynamically more stable orthorhombic OsB₂. The densification was not complete at this temperature, as shrinkage of the material was not completed (**Fig. 1(C)**), resulting in high

Fig. 5 SEM images (A), (B), EBSD grain orientation maps (C), (D), and pole figures (E), (F) of sintered ZrB₂ (A), (C), (E) and HfB₂ (B), (D), (F) ceramics.

residual porosity ($\sim 27\%$) and a relatively small submicron grain size after densification. The porosity and grain size of OsB₂ ceramics are listed in [Table 1](#). Electron backscatter diffraction (EBSD) was used to identify the structure of OsB₂ after sintering and, very similar to the X-ray analysis data, it was identified that 77.3 wt% of the grains belonged to the ReB₂-type OsB₂, while the remaining 22.7 wt% were identified as orthorhombic OsB₂ ([Fig. 6](#)). Some areas on the map ([Fig. 6\(A\)](#)), apparent as a black phase, were identified either as pores or as the rhombohedral boron (B) phase; however, it was not possible to index B due to a lack of signal and the limiting sensitivity of the equipment. The grain orientation of OsB₂ is shown in [Fig. 6](#), where no texture is possible to identify. Scanning Transmission Electron Microscopy (STEM) was also employed to analyze the OsB₂ ceramic structure after SPS and the micrographs of individual grains with hexagonal and orthorhombic structure are shown in [Fig. 7](#) along with their selected area diffraction patterns. The hexagonal grain, shown in [Fig. 7](#), exhibits the presence of well-defined linear defects, which could be either dislocations or even tiny microcracks present along the length of the grain. The presence of these defects is an indication of the brittle nature of OsB₂, since such defects might easily facilitate the brittle failure of the grain and be responsible for high overall brittleness of the OsB₂.

While it was possible to synthesize almost phase pure non-equilibrium ReB₂-type hexagonal OsB₂ and even partially retain this phase after high temperature sintering, only a small fraction of hexagonal IrB₂ phase was synthesized and retained after high energy ball milling of Ir and B powders ([Xie et al., 2016a](#)). The major phase was the thermodynamically stable IrB_{1.35} phase; however, small quantities of ReB₂-type IrB₂ phase were also detected along with IrB monoboride. A STEM micrograph of Ir-B particles after 30 h of milling and 48 h of annealing at 1050°C *in vacuo* (~ 7 Pa) are presented in [Fig. 8](#). The micrograph shows a mixture of different Ir-B phases, such as pure B, IrB_{1.35}, IrB and IrB₂ as shown in [Fig. 8\(A\)](#), where the ReB₂-type hexagonal IrB₂ structure was found among the particles shown in [Fig. 8\(A\)](#). The corresponding bright and dark field STEM images of the hexagonal IrB₂ phase oriented in the [100] direction are shown in [Fig. 8\(B\)](#) and [\(C\)](#), respectively. In addition to 30 h of high energy ball milling and 48 h of high temperature annealing at 1050°C *in vacuo*, a mixture of Ir and B nanoparticles was also milled for 90 h under similar high energy ball milling conditions ([Xie et al., 2016a](#)). A HRTEM image of a hexagonal IrB₂ nanoparticle is shown in [Fig. 9](#), where a Fourier transform (FFT) pattern shows the orientation of this particle in the [121] direction. Annealing for 72 h at

1050°C *in vacuo* of the Ir-B phases resulted in Ir atom segregation from the IrB₂ lattice along disoriented defective domains (Fig. 10). STEM and HAADF STEM images are presented in Fig. 10(A) and (B). Magnified images of selected lattice fringes of IrB₂ are shown in Fig. 10(C)–(E). The magnification is identical for the (C), (D) and (E) images. This segregation of Ir atoms along the disordered domains resulted in the formation of rows of single Ir atoms as well as Ir segregation into separate clusters, which might be important for use of this material as an active Ir based catalyst (Xie *et al.*, 2015c).

Nanoindentation of ZrB₂, HfB₂ and OsB₂ Ceramics

Methodology

Nanoindentation of ZrB₂ and HfB₂ ceramics was performed using a Hysitron TI Premier machine equipped with a Berkovich diamond tip at the University of Central Florida (UCF), Orlando, USA. A total of 25 indents were produced on the polished

Fig. 8 STEM of the Ir and B mixture after 30 h of ball milling and 48 h of annealing (A). The corresponding bright and dark field STEM images of the hexagonal IrB_2 phase oriented in $[100]$ direction are shown in HRSTEM ((B) and (C), respectively). Reproduced from Xie, Z., Blair, R., Orlovskaya, N., *et al.*, 2016a. In search of the elusive IrB_2 : Can mechanochemistry help? *Journal of Solid State Chemistry* 233, 108–119.

calculate the hardness and Young's modulus of ZrB₂, HfB₂ and OsB₂, assuming the diamond indenter and sample to be an elastically isotropic solid. The reduced modulus values, calculated for the diamond indenter – specimen system, is defined as:

$$\frac{1}{E_r} = \frac{1 - \nu_s^2}{E_s} + \frac{1 - \nu_i^2}{E_i} \quad (1)$$

where ν is the Poisson's ratio, E is the Young's modulus, and the subscripts s and i refer to the specimen and the indenter, respectively. From the unloading part of the load-displacement curve the effective E_r can be estimated as:

$$E_r = \frac{\sqrt{\pi}}{2} \frac{S}{\sqrt{A}} \quad (2)$$

where S is taken as the slope of the unloading curve at the beginning of unloading and A is the projected contact area. A is determined from a nanoindenter area function $A(h_c)$, where h_c is the distance from the contour of contact to the maximum penetration depth. The following expression was proposed for the computation of h_c (Oliver and Pharr, 1992):

$$h_c = h - \frac{3P}{4S} \quad (3)$$

where h and P are the displacement and the load from measured nanoindentation diagram. It was determined that the area function $A(h_c)$ can be presented by the following equations:

$$A(h_c) = C_0 h_c^2 + C_1 h_c + C_2 h_c^{1/2} + C_3 h_c^{1/4} + C_4 h_c^{1/8} + C_5 h_c^{1/16} \quad (4a)$$

$$A(h_c) = -3.14 h_c^2 + 1397 h_c [\text{nm}^2] \quad (4b)$$

for Berkovich and spheroconical diamond nanoindenters, respectively.

Note that C_0 , C_1 , C_2 , C_3 , C_4 , and C_5 are the coefficients determined for a given Berkovich indenter from a series of indents at various contact depths in a sample of known elastic modulus (typically fused quartz), and $C_0 = 24.5$ for an ideal Berkovich probe. The hardness of the material was determined using the following standard equation:

$$H = \frac{P}{A} \quad (5)$$

where P is the maximum load of nanoindentation, A can be found using Eq. (4) or from a SEM image of the corresponding impression.

The mean contact pressure was calculated for a Berkovich tip indenter as (Kuliev et al., 2020):

$$p_i = \frac{P_i}{A_i} \quad (6)$$

where P_i is the current indentation load on the load – indenter displacement diagram (P_i may be taken directly from indentation data points); A_i is the contact area that may be determined by using the area function:

$$A_i = C_0 (h_c)_i^2 + C_1 (h_c)_i + C_2 (h_c)_i^{1/2} + C_3 (h_c)_i^{1/4} + C_4 (h_c)_i^{1/8} + C_5 (h_c)_i^{1/16} \quad (7)$$

where $(h_c)_i$ is the contact depth corresponding to P_i which can be calculated as:

$$(h_c)_i = h_i - (h_e)_i \quad (8)$$

Table 4 Mechanical properties of ZrB₂, HfB₂, and OsB₂ by nanoindentation

Composition Indenter	ZrB ₂ Berkovich	HfB ₂ Berkovich	OsB ₂ Spheroconical
<i>H</i> , GPa	43 ± 3	34 ± 11	31 ± 9
<i>E_r</i> , GPa	349 ± 8	322 ± 48	446 ± 87
Poisson ratio	0.12	0.13	0.18
<i>E</i> , GPa	494 ± 11	440 ± 66	574 ± 112
<i>I_E</i>	0.12	0.11	0.05
<i>I_D</i>	0.29	0.3	0.45
Pop-in	No	Yes	Yes

where h_i is the total measured indenter displacement corresponding to P_i (h_i may be taken directly from indentation data points); $(h_e)_i$ is the corresponding elastic deflection (Novikov *et al.*, 1996; Oliver and Pharr, 1992; Sneddon, 1965):

$$(h_e)_i = (h_e)_{\max} \sqrt{\frac{P_i}{P_{\max}}} = \varepsilon \frac{P_{\max}}{S} \sqrt{\frac{P_i}{P_{\max}}} \quad (9)$$

where $(h_e)_{\max}$ is the elastic deflection at maximum load $P_{\max}$ of the indentation diagram; S is the slope at the beginning of the unloading portion of the indentation diagram which is the unloading stiffness; ε is a constant that depends on the indenter's geometry ($\varepsilon=0.75$ for Berkovich indenter). After calculation the mean contact pressure can be plotted against the contact depth.

From the contact area A for spherical indentation the radius of contact for certain h and P can be calculated as:

$$a = \sqrt{\frac{A}{\pi}} \quad (10)$$

Once the radius is calculated, then the following equations were used for conversion of load-displacement into indentation stress-indentation strain plots (Pathak *et al.*, 2008):

$$\sigma_{\text{ind}} = \frac{P}{\pi a^2} \quad (11)$$

and

$$\varepsilon_{\text{ind}} = \frac{4}{3\pi} \frac{h}{a} \quad (12)$$

By converting load-displacement data into indentation stress-indentation strain plots, the elastic part:

$$\sigma_{\text{ind}} = E_r \varepsilon_{\text{ind}} \quad (13)$$

of the loading segment of the nanoindentation diagram can be revealed as well as a yield point, where the deviation from linear behavior and the onset of plastic deformation can be visualized.

The material can be also characterized by elasticity and ductility indices. The elasticity index is defined as (Xie *et al.*, 2015b):

$$I_E = H/E_r \quad (14)$$

where H is the hardness and E_r is the reduced modulus (Sakai, 1999; Malzbender, 2003; Chen and Bull, 2006). The elasticity indices of the most brittle ceramics range from 0.3 to 0.05 and of ductile metals from 0.005 to 0.001 (Sakai, 1999; Malzbender, 2003). The indentation ductility index is defined as follows (Sakai, 1999):

$$I_D = \frac{U_r}{U_t} = \frac{h_r}{h_{\max}}, \quad (15)$$

where U_r is the consumed energy for creating the residual impression, U_t is the total work at maximum load, h_r is the residual depth of indentation as measured from the load-displacement diagram after complete unloading, $h_{\max}$ is the maximum depth of indentation at maximum load. The ductility index must be 1 for a purely plastic (purely ductile) body without elastic recovery during unloading and 0 for a purely elastic body exhibiting a complete unloading recovery in an elastic manner. With the increase in the elasticity index, the ductility index decreases from 1 to 0 (Sakai, 1999).

Hardness, Young's Modulus, Indentation Stress – Indentation Strain Behavior, Elasticity and Ductility Indices of ZrB₂, HfB₂ and OsB₂

The average hardness and Young's modulus values of ZrB₂ were measured to be 43 ± 3 GPa and 494 ± 11 GPa, respectively (Table 4). Such high values of hardness and elastic modulus can be explained by the very high density/short bond lengths of ZrB₂. A typical load-displacement nanoindentation diagram of ZrB₂ is shown in Fig. 11(A), and almost identical deformation behavior was observed for all indentations. One characteristic feature of all these diagrams is the lack of any discontinuities both upon loading and upon unloading during nanoindentation. On conversion of load-displacement plots into a mean contact pressure - indentation contact depth diagram (Fig. 11(B)) the maximum mean contact pressure was in the range of 47–51 GPa,

Fig. 11 Nanoindentation load-displacement (A) and mean contact pressure-contact depth (B) curves for ZrB₂ during loading and unloading.

which related very well to the average hardness value of ZrB₂. Elasticity and ductility indices of ZrB₂ ceramics were also calculated (Table 4).

The average hardness and Young's modulus values of HfB₂ were measured to be 34 ± 11 GPa and 440 ± 66 GPa. While these are still considered to be very high values of mechanical properties for HfB₂, they are lower than those reported for ZrB₂. Such lower values can possibly be explained by the presence of porosity in the sample but also by the intrinsic behavior of HfB₂. A typical load-displacement nanoindentation diagram of HfB₂ is shown in Fig. 12(A) and the corresponding mean contact pressure – contact depth diagram is shown in Fig. 12(B). Unlike ZrB₂, the deformation behavior of HfB₂ during nanoindentation was characterized by the presence of “pop-in” events during loading. These “pop-ins” were almost always present and they characterized a small mean contact pressure drop, possibly due to crack formation and propagation to relieve tensile stress at the corners of the Berkovich indents during indentation. The maximum mean contact pressure was in the range of 38–41 GPa, which again, similar to the ZrB₂ values, represents very well the average hardness values of HfB₂. The mean contact pressure values measured both for ZrB₂ and HfB₂ are above the average hardness values measured by dividing maximum load by the contact area of impressions. Elasticity and ductility indices of HfB₂ ceramics were also calculated and they are presented in Table 4.

The average hardness and Young's modulus values of OsB₂ were measured to be 31 ± 9 GPa and 574 ± 112 GPa, respectively. This newly identified hexagonal OsB₂ material exhibited quite high hardness and very high stiffness, which corresponds very well with high valence electron density present in this compound (Xie *et al.*, 2015b; Chung *et al.*, 2008). The typical load-displacement nanoindentation diagram of OsB₂ is shown in Fig. 13(A). As can be seen, “pop-in” events are present during the loading portion of the deformation plot. It was found that out of all 50 load-displacement deformation plots, 36 of them featured “pop-in” events at the loading portion of the plots. The “pop-in” events are present even more prominently, when load displacement diagrams are recalculated into indentation stress – indentation strain plots (Fig. 13(B)). From Fig. 13(B) it can

Fig. 12 Nanoindentation load-displacement (A) and mean contact pressure-contact depth (B) curves for HfB₂ during loading and unloading.

be seen that a very high stress level existed below the spheroconical diamond indenter during indentation, and thus such conversion makes it possible to see the indentation deformation behavior of OsB₂ during contact loading. The “yield” stress could also be estimated from such indentation stress – indentation strain diagrams and for OsB₂ an example of “yield” stress equal to 20 GPa evaluated from the diagram is shown in Fig. 13(B). The average “yield” stress value calculated using all 36 indentation plots was equal to 23 ± 7 GPa. The nanoindentation experiments indicated that OsB₂ phases are relatively hard and rather stiff with high yield stress values, as determined by their hardness, Young’s modulus, “yield” stress, and indentation stress – indentation strain deformation behavior.

The elasticity and ductility indices of ZrB₂, HfB₂ and OsB₂ ceramics were calculated according to Eqs. (14) and (15). The results of the calculation are presented in Table 4. The computed elasticity index I_E was high and equal to 0.12 and 0.11 for ZrB₂ and HfB₂ ceramics, respectively, while it was significantly lower and equal to 0.05 for OsB₂. The computed ductility index I_D was equal to 0.29 and 0.30 for ZrB₂ and HfB₂, respectively; however the value was higher and equal to 0.45 for OsB₂. For comparison, the I_E of Al₂O₃, SiC and Si₃N₄ ceramics are equal to 0.08, 0.13, and 0.175, respectively, and their I_D values are equal to 0.68, 0.57, and 0.59, respectively (Sakai, 1999). For glass, I_E and I_D are equal to 0.19 and 0.54, respectively. Thus, the elasticity indices of ZrB₂ and HfB₂ are very close in values to those of SiC ceramics, but the I_E of OsB₂ is located in the lower range for all materials. Ductility indices of all three diboride ceramics are much lower, in comparison even with a glass. Such low values of both indices of ZrB₂, HfB₂ and OsB₂ reflect the highly brittle nature of these ceramics.

Fig. 13 Load-displacement (A) and recalculated indentation stress – indentation strain (B) diagrams produced by nanoindentation of polished OsB₂ surface where “pop-in” events were present during the loading portion of the load-displacement curve. Reproduced from Xie, Z., Lugovy, M., Orlovskaya, N., *et al.*, 2015b. Hexagonal OsB₂: Sintering, microstructure and mechanical properties *Journal of Alloys and Compounds* 634, 168–178.

Summary

The processing, structure, and properties of ZrB₂, HfB₂, OsB₂, and IrB₂ diboride ceramics have been presented. While ZrB₂ and HfB₂ powders are commercially available, OsB₂ and IrB₂ have been synthesized by mechanochemistry for the first time. ZrB₂, HfB₂, and OsB₂ can be densified using the Spark Plasma Sintering technique. Almost fully dense ZrB₂ was sintered at 2100°C, 15 MPa and 35 min dwell time; however densification of HfB₂ under the same conditions was limited and ~9% of porosity was retained after sintering. Such difference indicates that ZrB₂ is easier to sinter in comparison with HfB₂. An attempt to sinter hexagonal OsB₂ was successful; however only ~80% of hexagonal OsB₂ was retained after sintering at 1500°C, 50 MPa and 5 min dwell time, while the other ~20% was transformed into the thermodynamically stable orthorhombic OsB₂ phase. OsB₂ also contained a high amount of porosity (~27%), and thus more work on the optimization of the sintering conditions is required to achieve fully dense hexagonal OsB₂.

All four diboride compounds were studied by X-ray diffraction to determine their phase composition and lattice parameters. It was found that only ZrB₂ is a phase pure material with no secondary phase found, while HfB₂ contained HfB monoboride and HfO₂ as minor secondary phases. OsB₂ after sintering contained a mixture of the metastable hexagonal and thermodynamically

stable orthorhombic phases; however, the hexagonal ReB₂ type IrB₂ was not a major phase in a mixture of Ir-B phases, and only constituted 7.7 wt%, while the thermodynamically stable IrB_{1.35} was the major phase with an amount equal to 76.2 wt% with the rest of the mixture present as orthorhombic IrB monoboride. The microstructure of all four diborides were investigated by SEM, EBSD, and TEM techniques.

The mechanical properties, such as hardness, Young's modulus, indentation deformation behavior, and elasticity and ductility indices of ZrB₂, HfB₂, and OsB₂ ceramics were studied by nanoindentation. All three ceramics exhibited high hardness, which varied from 31 ± 9 GPa for OsB₂ to 43 ± 3 GPa for ZrB₂. Indeed, their Young's modulus values were also very high: 574 ± 112 GPa for OsB₂, 494 ± 11 GPa for ZrB₂, and 440 ± 66 GPa for HfB₂. It was found that ZrB₂ does not exhibit any "pop-in" events during loading and unloading, thus showing that this material is able to accommodate severe plastic deformation caused by nanoindentation using the sharp Berkovich indenter without microcracking or a phase transition. However both HfB₂ and, especially, OsB₂ experienced "pop-ins" during loading, which were most likely caused by microcracking due to appearance of high stresses. All three diboride compounds showed a very brittle nature as indicated by their elasticity and ductility indices. The mechanical behavior of IrB₂ and other Ir – B phases will be studied in the future, where purer IrB₂ powder will be synthesized and sintered using Spark Plasma Sintering or other relevant techniques.

This is a reprint of VM Orera, J Llorca, Directionally-Solidified Eutectic Oxide Ceramics, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.02355-9.

Excellent chemical stability in oxidizing atmospheres makes ceramic oxides suitable for high-temperature structural applications. However, the poor strength retention, creep resistance, and the presence of low melting point intergranular phases deteriorate the mechanical behavior of conventional ceramics above 1100 °C. Alternatively, single-crystal oxides present superior creep resistance up to 1500 °C but their strength is sometimes impaired due to slow crack growth. These limitations can be successfully eliminated in the directionally-solidified eutectic (DSE) ceramics grown from melt. DSE ceramic oxides are envisaged as ultra-high-temperature functional and structural materials, which may find use in structural applications, photonics, electronic devices, and magnetic applications and also as structured substrates (Llorca and Orera, 2006; Merino *et al.*, 2003).

This is the case for the sapphire-based $\text{Al}_2\text{O}_3/\text{c-ZrO}_2$, $\text{Al}_2\text{O}_3/\text{Y}_3\text{Al}_5\text{O}_{12}/\text{YSZ}$, $\text{Al}_2\text{O}_3/(\text{RE})\text{AP}$ (RE (rare earth) = Sm, Eu, Gd), and $\text{Al}_2\text{O}_3/(\text{RE})\text{AG}$ (RE = Sm–Lu, Y) eutectics. These systems consist of cubic zirconia, perovskite, or garnet phases of micron or nanometer size, dispersed into the continuous sapphire single crystalline phase. The combination of the outstanding creep behavior of Al_2O_3 along its *c*-axis with a huge amount of clean and strong grain boundaries, characteristic of the eutectic solids, results in a new set of ceramic oxides with excellent creep behavior and good mechanical properties up to 1700 °C even in corrosive environments. This makes sapphire-based eutectics useful in the fields of aeronautics and aerospace, gas turbines, and power generation industries (Waku *et al.*, 1997).

The present article briefly reviews these DSE oxides and also some spinel- $(\text{MgAl}_2\text{O}_4)$ and ZrO_2 -based eutectics under the light of recent developments. The emphasis is on the relationships between growth parameters and microstructure, hence on the influence of the microstructure in the mechanical properties of these compounds.

Oxide Eutectics: Composition Microstructure and Preparation

Microstructure

Eutectics grown from the melt give rise to homogeneous, highly-structured dense materials. The basic microstructure of a regular eutectic consists of nonfaceted phases either single-crystal rods or lamellae embedded in a single-crystal matrix as depicted in Figures 1 and 2. In the simplest case of isotropic surface energy, fibers instead of lamellae are found for volume fractions of the minority phase less than 28%. When the fusion entropy is high, the eutectic microstructure is complex because the growth interface cannot deviate from certain crystal orientations and faceted phases are produced (Hunt and Jackson, 1966). In the DSE oxides described in this article, simple regular microstructures are an exception more than a rule. The tendency of Al_2O_3 to develop facets leads to complex microstructure morphologies where cells with degenerated lamellae or rod eutectic structures are usually interspersed in regular regions in the same sample (Orera and Peña, 2012).

The most favorable situation from the point of view of mechanical properties and high-temperature stability (Peña *et al.*, 2002) is when the phases are continuously entangled in a three-dimensional interpenetrating (TDI) network as depicted in Figure 3. This homogeneous and fine microstructure free of grain boundaries are produced under low solidification rates for which the growth mode is more co-operative. In contrast with metallic eutectics, TDI microstructures are also found in faceted/faceted oxide systems. In case of facets, the microstructure exhibits the aspect of Figure 4 referred to in the literature as Chinese Script (CS) microstructure. Recently, superplastic behavior has been observed in some nanofibrillar directionally-solidified ternary eutectic oxides grown at high growth rates (Pastor *et al.*, 2013).

The microstructure size is growth-rate dependent. In the simple, nonfaceted/nonfaceted regular eutectics, the interphase spacing λ depends on the solidification rate R as $\lambda^2 \cdot R = C$, where C is known as the interphase spacing law constant. In the case of DSE oxides, the microstructure size always decreases with increasing growth rate. For eutectics with simple regular or TDI microstructures, the solidification rate rule still holds. Interphase spacing is typically in the 0.2–10 μm range. The composition, melting temperature, and C -value for the oxide eutectics covered in this article are given in Table 1. The physical properties of the component phases are summarized in Table 2.

Preparation

For homogeneous growth, large axial thermal gradients are usually needed to keep micro- and macroscopically flat solid–liquid interfaces during growth, thus preventing cellular growth (Ashbrook, 1977). Among the different directional solidification

[†]This chapter is dedicated to the memory of Víctor Manuel Orera Clemente.

procedures to grow oxide ceramic eutectics (Stubican and Bradt, 1981), the Bridgman method uses relatively low thermal gradients ($< 10^2$ K cm⁻¹) and low growth rates (< 100 mm h⁻¹) resulting in bulk samples with interphase spacing larger than 1 μm. Micro-pulling down (μ -PD), Stepanov, and edge-defined film growth (EFG) methods with thermal gradients of the order of 10^3 K cm⁻¹ allow the growth of shaped samples at relatively high growth rates (up to a few m h⁻¹). Processing techniques based on floating zone are crucibleless methods in which a relatively small amount of sample volume is melted by the action of lasers, or r.f. or light waves. Thermal gradients can be very large, up to 10^4 K cm⁻¹, allowing fast growing rates in the coupled growth regime. These

methods are suitable to grow fibers down to tens of microns in diameter. Some interesting variations of the laser float zone method (LFZ) have been recently reported, which take advantage of laser spots in the form of narrow lines to produce directional solidified eutectic plates up to 0.5 mm in thickness (Orera *et al.*, 2012). This latter method is very promising for coatings and surface processing (Larrea *et al.*, 2002, 2005).

Crystallography

In eutectics the single-crystal phases grow along well-defined crystallographic directions generally corresponding to interfacial energy minima. Nevertheless, in most of the DSE oxides presented here, relationships among the crystallographic orientations do not necessarily correspond to surfaces of lowest interfacial energy. In fact, the large fusion entropy and anisotropy of Al_2O_3 enhance the contribution of growth kinetics in developing the interfaces. The growth-rate dependence of the microstructure morphology can be roughly understood as follows. At low growth rates, a planar solidification front is formed and coupled growth results in homogeneous eutectic TDI microstructures. As the growth-rate increases, colonies with ordered eutectic structures in the

center start to develop. Finally, eutectics grown at very high growth rates show a cellular structure comprising very elongated cells parallel to the growth axis. The microstructure within the cells consists of very fine TDI resulting from the co-operative growth of both phases, as in the rods grown at low rates. Multiple orientation relationships have been reported for these systems, which can be, to some extent, modified by appropriate changes of the growth parameters. This is the case, for example, of Al₂O₃–YAG (Table 3).

The mutual orientation of the component phases has a marked influence on the residual stresses, microstructure morphology, stability, and mechanical properties of the material. This is the case for some simple DSE oxides such as MgO/MgSZ, MgAl₂O₄/MgO, and CaZrO₃/CaSZ although in the latter the relative orientation between lamellae may accommodate some misalignment (see Table 3).

Mechanical Properties

The properties of primary importance for high-temperature applications are the resistance to chemical and thermochemical corruptions, the maximum operating temperature, mechanical properties such as stiffness, toughness and hardness, thermal conductivity and expansion, and density. Impact, erosion, wear resistance, as well as creep resistance are also important for some applications. The components of the DSE oxides described in this article (crystalline sapphire, oxide perovskites, oxide garnets, spinel, and zirconia) are among the best high-temperature materials for oxidizing ambient. The decrease of the melting point of DSE oxides (see Table 1) is fully compensated by the increase in strength and creep resistance due to the presence of large surface fraction of clean, strong interfaces as well as by the lack of susceptibility to stress corrosion cracking. Table 4 summarizes some relevant mechanical properties of DSE oxides. The best mechanical properties at ambient and elevated temperatures are found in the binary Al₂O₃–YAG and the pseudo-binary Al₂O₃–ZrO₂(Y₂O₃) systems and are described in detail below.

Al₂O₃–YAG

This eutectic presents an excellent potential as structural material for high-temperature applications in oxidizing environments due to (1) the good creep resistance of both phases, (2) the strong interfacial bonding between the eutectic domains, (3) their interpenetrating morphology which impedes free dislocation motion in each phase, (4) the absence of amorphous phases at the interfaces, and (5) its inherent microstructural and chemical stability up to temperatures very close to the eutectic point. Matson and Hecht (1999), Waku *et al.* (2001), and Pastor *et al.* (2004) have measured the strength at ambient temperatures in eutectics with domain thickness, λ , in the range 0.2 to 25 μ m and their results are compiled in Figure 5. The strength is proportional to $1/\sqrt{\lambda}$, indicating that the critical defects responsible for brittle fracture depend on the size of the eutectic domains. In fact, when the critical defects are semicircular surface cracks with a radius equal to λ , the eutectic tensile and flexure strength, σ_u , is given by (according to fracture mechanics)

$$\sigma_u = \frac{\sqrt{\pi} K_C}{2 \sqrt{\lambda}} \quad [1]$$

Table 4 Flexural strength σ_f and toughness K_{IC} of DSE eutectics

Components	σ_f (GPa) at 300 K	σ_f (GPa) at the temperature indicated	K_{IC} MPa m ^{1/2}
YSZ/Al ₂ O ₃	1.55	0.9 (1600 K)	5–7.8
Al ₂ O ₃ /Y ₃ Al ₅ O ₁₂	1.9	1.7 (1700 K)	2.0
CaZrO ₃ /CaSZ	0.22		
MgO/MgSZ	0.3		
Al ₂ O ₃ /Er ₃ Al ₅ O ₁₂	2.7	2.7 (1600 K)	1.9
Al ₂ O ₃ /EuAlO ₃		0.32 (1775 K) [†]	
Al ₂ O ₃ /GdAlO ₃		0.28 (1775 K) [†]	
MgAl ₂ O ₄ /MgO		0.2 (1875)	
Al ₂ O ₃ /Y ₃ Al ₅ O ₁₂ /YSZ	4.0	2.5 (1450)	3.3

[†]Tensile strength.

where K_{IC} is the fracture toughness. The linear fit to the experimental results in Figure 5 is obtained with $K_{IC} = 1.6 \text{ MPa m}^{1/2}$, and this value is only marginally lower than the ambient temperature fracture toughness of Al₂O₃-YAG, which is close to $2 \text{ MPa m}^{1/2}$, and independent of the orientation and domain size (Ochiai et al., 2001; Pastor et al., 2004). Of course, the moderate toughness of the eutectic is also its Achilles' heel for, any chemical or mechanical processes that induce surface damage, may degrade the strength considerably.

The flexure strength of the Al₂O₃-YAG eutectics has been measured as a function of temperature in air and in Ar (Waku et al., 2001; Pastor et al., 2004). Average values, together with the corresponding standard errors, are plotted in Figure 6. The eutectics with large domain size maintained their flexure strength up to 1900 K, very close to the eutectic temperature of 2100 K. Eutectics with an average domain size of 1 μm and below suffer from a significant reduction in the strength at temperatures above 1700 K due to homogeneous microstructure coarsening. In addition, Matson and Hecht (1999) reported that the tensile strength of small diameter fibers shows a marked reduction in strength after annealing in air at moderate temperatures (above 1400 K). The fracture of Al₂O₃-YAG fibers at high-temperature, or after annealing, was controlled by the nucleation of defects, which developed as a result of a reaction between the eutectic components and silica-containing dust and dirt particles from the environment. The eutectics are extremely flaw-sensitive because of their poor fracture toughness and the localized coarsening of the microstructure

Figure 5 Strength of Al_2O_3 -YAG DSE at ambient temperature as a function of the thickness, λ , of eutectic domain.

Figure 6 Flexure strength of Al_2O_3 -YAG DSE as a function of temperature. The legend indicates the environment used for the test and the thickness of the eutectic domain in the microstructure.

due to the reaction of the eutectic oxides with the environment is responsible for the degradation of the tensile properties, which is the most noticeable in fibers with a large specific surface.

The creep resistance of coarse-grained and single-crystal Al_2O_3 -YAG eutectics along the solidification direction in air was measured by Parthasarathy *et al.* (1993) and Harada *et al.* (2004). The minimum creep rate, $\dot{\epsilon}$, is plotted in Figure 7 as a function of the applied stress, σ , and both sets of experiments (in single-crystal and coarse-grained DSE) indicate that the eutectic creep follows a power-law relationship as

$$\dot{\epsilon} = A\sigma^n \exp\left(-\frac{Q}{RT}\right) \quad [2]$$

where T is the absolute test temperature, n the stress exponent, and Q the activation energy of the physical mechanism responsible for creep deformation. The stress exponents are in the range 5–6 for both materials at temperatures above 1800 K and the activation energies are in the range 650–800 kJ mol^{-1} in the coarse-grained material and slightly higher (800–1000 kJ mol^{-1}) in the single-crystal eutectic. These results are compatible with creep deformation controlled by dislocation motion in each phase

Figure 7 Minimum creep rate as a function of the applied stress in Al_2O_3 -YAG DSE with coarse-grained (CG) and single-crystal (SC) microstructure.

Figure 8 Ambient temperature strength of Al_2O_3 - $\text{ZrO}_2(\text{Y}_2\text{O}_3)$ DSE rods and fibers as a function of the yttria content expressed by $Y = \text{mol of } \text{Y}_2\text{O}_3 / (\text{mol } \text{ZrO}_2 + \text{mol } \text{Y}_2\text{O}_3)$.

induced by lattice diffusion in the single-crystal eutectic, and this assumption was supported by transmission electron microscopy studies showing evidence of dislocation activity in both phases, particularly in Al_2O_3 .

Al_2O_3 - $\text{ZrO}_2(\text{Y}_2\text{O}_3)$

The ambient temperature strength of Al_2O_3 -YAG is essentially a function of the domain thickness, whereas that of Al_2O_3 - $\text{ZrO}_2(\text{Y}_2\text{O}_3)$ depends primarily on (1) the Y_2O_3 content, which controls the structure of the polymorphic variant of zirconia within the eutectic together with the residual stresses and (2) on the spatial distribution of both phases, which varies with the growth rate.

The effect of the Y_2O_3 content on the ambient temperature strength has been studied in hypo-eutectic Al_2O_3 - $\text{ZrO}_2(\text{Y}_2\text{O}_3)$ fibers (Farmer and Sayir, 2002) and eutectic Al_2O_3 - $\text{ZrO}_2(\text{Y}_2\text{O}_3)$ rods (Llorca et al., 2004). The results of these investigations are plotted in Figure 8, where Y stands for the mol% of Y_2O_3 dissolved in the $\text{ZrO}_2 + \text{Y}_2\text{O}_3$ phase. The poorest mechanical properties are always found in the yttria-free samples, where zirconia has transformed from tetragonal to monoclinic upon cooling from the processing temperature. The volumetric change associated with the transformation generates large tensile residual stresses in the Al_2O_3 continuous phase, and impaired the eutectic strength. Tetragonal ZrO_2 is found in the eutectics with $Y \approx 3\%$ as the tetragonal to monoclinic transformation is completely suppressed by yttria. As a result, the thermo-elastic residual stresses

Figure 9 Influence of the microstructure morphology on the flexure strength of $\text{Al}_2\text{O}_3\text{-ZrO}_2(\text{Y}_2\text{O}_3)$ DSE rods. The number beside each experimental point indicates the yttria content expressed in Y(%).

Figure 10 Flexure strength of $\text{Al}_2\text{O}_3\text{-ZrO}_2(\text{Y}_2\text{O}_3)$ DSE rods as a function of temperature.

generated upon cooling are compressive in the Al_2O_3 phase and the strength is almost doubled with respect to the yttria-free samples. Further increase in the yttria content leads to the stabilization of the cubic ZrO_2 phase in the eutectic. The thermal expansion coefficients of tetragonal and cubic ZrO_2 being very similar, the thermal residual stresses do not vary significantly as the yttria content increases above $Y=3\%$.

The intercolony and intercellular regions contained coarse ZrO_2 particles of irregular shape, as well as cracks and pores, and their thickness increases with the yttria content due to the segregation of this oxide to the intercolony and intercellular regions during solidification. The flexure strength of $\text{Al}_2\text{O}_3\text{-ZrO}_2(\text{Y}_2\text{O}_3)$ DSE with various microstructures and $Y \approx 3\%$ is plotted in [Figure 9](#) as a function of the width perpendicular to the growth axis of the relevant feature, either lamellae, cells, or colonies, that characterizes the microstructure. The highest strength is measured in the eutectics made up by a fine dispersion of ZrO_2 lamellae within the continuous Al_2O_3 matrix, while materials with colony or cell structure attain lower strengths which decrease with the cell or colony width ([Peña et al., 2006](#)). The critical defects, promoting fracture in the eutectics with cell and colony morphologies, are localized at the intercellular and intercolony regions ([Pastor et al., 2008](#)).

The strength retention at high-temperature of $\text{Al}_2\text{O}_3\text{-ZrO}_2(\text{Y}_2\text{O}_3)$ DSE has been measured by [Llorca et al. \(2004\)](#) and [Pastor et al. \(2001\)](#), and the average flexure strength is plotted in [Figure 10](#) for three eutectics with different Y_2O_3 contents. The materials which contain ZrO_2 in either tetragonal ($Y=3\%$) or cubic ($Y=9\%$) form do not experience any noticeable degradation up to 1300 K retaining up to 70–80% of the ambient temperature strength at 1700 K. This excellent high-temperature behavior is similar to that found in $\text{Al}_2\text{O}_3\text{-YAG}$, although the strength reduction starts at lower temperatures because the ZrO_2 resistance to plastic deformation is lower than that of YAG. On the contrary, the eutectic with monoclinic ZrO_2 experiences a marked degradation in

strength at very low temperature accompanied by the appearance of longitudinal cracks in the fracture surfaces. These cracks are generated by the build-up of tensile residual stresses in the ZrO_2 phase resulting from the differences in the thermal expansion coefficients of monoclinic ZrO_2 and Al_2O_3 as well as from the negative volumetric strain in the ZrO_2 when the martensitic transformation is reversed.

Summary

Directionally-solidified eutectic ceramic oxides are a family of *in situ* composite materials with a homogeneous and stable microstructure, whose morphology and size can be tailored by processing. Their hardness and strength at ambient temperature are comparable to or even better than those obtained in conventional structural ceramics. Additionally, due to the presence of large amounts of clean, strong interfaces and to the homogeneity of the microstructure, DSE maintains the mechanical properties up to temperatures very close to the eutectic point even in oxidizing environments. As compared with other ceramic oxides, DSE oxides show good thermal shock resistance and fracture toughness, although they do not attain the outstanding values measured in some carbides and borides. The most interesting DSE oxides for structural applications are those containing corundum, in particular Al_2O_3 -YAG and Al_2O_3 -YSZ, which offer excellent strength retention and creep resistance in the range 1400–1600 °C. Good mechanization and fabrication efficiency of structural components as compared with sintered engineering ceramics make these materials very promising candidates for high-temperature structural applications in oxidizing environments.

Overview: High-Performance Ceramics and Ceramic Composites

Michael Pomeroy, Bernal Institute, University of Limerick, Limerick, Ireland

© 2021 Elsevier Inc. All rights reserved.

This section is devoted to ceramic matrix composites (CMC) and ceramics for use aggressive environments, as well as joining of ceramics. The composites part begins with a chapter by Fantozzi and Chevalier which provides an excellent overview of reinforcement mechanisms in ceramics: transformation toughening, microcracking, crack deflection and crack bridging as well as whisker reinforcement. The chapter then goes on to review the state of the art knowledge of zirconia toughened composites, whisker composites, particle and platelet reinforced composites and finally carbon nanotube and graphene reinforced ceramic composites. For each type of composite, Fantozzi and Chevalier outline improvements in mechanical properties e.g., toughness, hardness, modulus, creep resistance induced by introducing reinforcements into a ceramic matrix. In addition, they indicate the mechanisms by which the mechanical properties are improved. The chapter by Thompson and Harmer describes alumina-silicon carbide nanoparticle composites. The chapter gives an excellent background to the development of nanocomposites and how the addition levels of SiC particles control the grain structure and grain size distribution of an alumina matrix. This chapter then goes on to report strengths of up to 1500 MPa realized by alumina-silicon carbide nanocomposites as well as toughness increases. Thompson and Harmer's chapter also shows how nanoparticle reinforcement reduces creep rates and typically changes fracture paths from intergranular for monolithic alumina to transgranular for the nanocomposite. This change of fracture path is related to improved wear and erosion resistance. Balázs *et al.* continue the theme of nanocomposites. However, the work they review is based upon a silicon nitride matrix reinforced with carbon nanotubes or graphene. Their chapter gives good insight into the processing of such nanocomposites without comminution of the nanostructured carbon reinforcements. Having looked at processing, the chapter then gives a very good overview of how the reinforcements are integrated into the matrix from transmission and scanning electron microscopy examination, as well as how they induce crack deflection. The chapter then goes on to look at the property improvements afforded by carbon nanostructure reinforcements, noting the importance of avoiding reinforcement agglomeration during processing. Agglomerates act as defects, inducing lower strengths for example, whereas well distributed carbon nanostructures act as reinforcements, increasing strength and indeed toughness. Following the papers on fine scale reinforcements, the chapter by Krenkel *et al.* increases the scale of reinforcement to the chopped or short fiber scale. Having addressed the mechanisms of short fiber reinforcement, including fiber/matrix interfacial debonding and matrix/fiber load transfer, the chapter is then able to show the importance of short fiber aspect ratio. One clear advantage of short fiber reinforcements is that the resulting composites are generally anisotropic. Krenkel *et al.* then review estimations of ceramic matrix composite strength and stiffness parameters before looking at how non-oxide CMCs are fabricated and used as well as reviewing their properties. The chapter finishes by looking at manufacturing routes, properties and applications of oxide matrix CMCs. Throughout it is made clear that short fiber CMCs cannot compete with long fiber CMCs in terms of strength and stiffness. However, the relative ease of fabricating complex components from short fiber CMCs means that they are used in high volume throughput components e.g., automobile brake disks.

Two chapters by Boccaccini *et al.* follow, the first of which describes the constitution of glass and glass ceramic matrix composites with particulate, whisker, platelet, chopped fiber, and continuous fiber reinforcements. As with the chapters by Fantozzi and Chevalier and Krenkel *et al.* toughening and strengthening mechanisms are discussed. The complexities associated with manufacture are discussed and typical manufacturing routes described. These routes include powder technology, infiltration of preforms via a number of precursors e.g., slurries, sol-gel/colloidal routes and polymers followed by debinding/pyrolysis steps and finally a pressureless sintering or pressure aided densification step yields a high density product. Boccaccini *et al.* also review the more recent use of 3D additive manufacturing routes. In their chapter on applications, Boccaccini *et al.* review the use of the various types of glass/glass ceramic matrix composites for aerospace, solid oxide fuel cell, biomedical, electronic substrate and structural applications.

The final five chapters in the sub-section on composites relate to continuous fiber composites, although the penultimate one discusses some elements of short fiber composites for ultra-high temperatures. They begin with the paper by Bunsell on high performance fibers, which is an excellent review of fiber manufacture and properties. The phenomenal property values for fibers become wholly evident to the reader. Thus, for example, Bunsell quotes strengths of more than 2.5 GPa for glass fibers as well as strains to failure of up to 5.3%. Bunsell also reviews carbon fibers, oxide fibers and silicon carbide fibers. The chapter by Wilson extends that of Bunsell with respect to spun oxide fibers. Wilson's chapter looks in depth at the production of alumina fibers via sol-gel and spinning routes. The resulting fibers have considerably higher strengths (up to 3 GPa) than alumina monoliths, as might be expected. Rebillet's chapter on long (continuous) fiber CMCs starts out with an excellent description of the various fiber woven architectures which fiber preforms can assume. It then explains how it is possible to achieve non-linear elastic behavior with this type of composite and deals with the importance of the interphase between the fiber and matrix in controlling this. Having explained the development of superior mechanical properties in long fiber composites, Rebillet goes on to cover the many various ways by which fiber preforms are infiltrated and inter-fiber spaces filled by a ceramic matrix material. In doing so, Rebillet is careful to look at how processing conditions require suitable control, in order to ensure that impregnation extends through the total thickness of the layered-up fiber assemblies. The chapter by Zoli *et al.*, which is devoted to ultra-high temperature ceramic matrix composites (UHTCMCs),

extends that of Rebillat by looking at other matrix types such as borides rather than SiC, to facilitate ultra-high temperature usage. This chapter reviews the fabrication of UHTCMCs without any sintering step by the use of polymer infiltration and pyrolysis, repeated impregnation by slurries and precursor gases (e.g., hafnium containing gases) as well as infiltration by molten but reactive silicides or metal – copper alloys which convert in the presence of carbon or boron to a ceramic matrix and a liquid metal which is expelled to the surface. The chapter then covers the manufacturing of materials with a sintering step and describes in detail the types of considerations which must be taken into account to achieve good densification with little or no fiber degradation. Zoli *et al.* also address ultra-high temperature short fiber UHTCMCs in this part. Having looked at functionally graded UHTCMCs Zoli *et al.* describe the benefits of adopting functionally graded composites with varying reinforcement contents. This approach, they show, increases toughness as well as reducing potential unwanted post-sintering residual stresses, which arise in long fiber UHTCMCs with a singular reinforcement content. The chapter concludes with sections on mechanical properties of UHTCMCs and their thermal-ablative resistance. In the final chapter in this sub-section, Chung's contribution deals with C/C composites. This chapter describes the constitution of C/C composites, how they are fabricated and their significant advantage as far as maximum use temperature in vacuum or argon is concerned (up to 2000°C). Chung draws attention to the need for SiC coatings if the C/C material is to be used in oxidizing environments. Thermal expansion mismatch between matrix and fiber carbons also causes a degradation of properties at high temperatures. In general, though the properties quoted for a commercial C/C composite by Chung appear modest, the fact that these properties can be maintained to very high > 2000°C gives such materials the potential to be used in very high temperature applications e.g., aerospace. Chung also draws attention to the self-monitoring and self-powering capability of C/C materials as well as their important ability to provide electromagnetic shielding.

Having looked at high performance ceramic CMCs, Section 8 then looks at the application of materials in space applications. The chapter by Twomey *et al.* documents the various requirements for the application of ceramic materials in space. Typical application areas are: propulsion systems for spacecraft, structures for launchers and spacecraft, thermal protection systems and substrates for space optics. The application range is quite significant, as is the range of ceramic materials used in space applications as Twomey *et al.* summarize and explain very well. This chapter also indicates the move towards space commercialization and thus the potential increase in use of ceramics in space. Although not specifically mentioned in the chapter by Kaiser *et al.* their coverage of gas purification and solid oxide cells are additional aerospace applications of ceramics. That said, the chapter by Kaiser *et al.* is devoted to porous ceramics for energy applications and covers catalysts, solid oxide cells and ceramic membranes for liquid and gas separation. In addition to describing the technologies and typical requirements of these applications, Kaiser *et al.* also describe typical manufacturing routes for relevant components. They then finally discuss structure-property relationships for ceramics employed in the three application areas concerned. In many instances, it is necessary to bond ceramic components to other ceramic components or metallic components. Fernie and Knowles review the various methods of bonding available. The chapter looks at mechanical methods, friction/ultrasonic methods and diffusion bonding for joining, as well as glass to metal sealing and bonding. Adhesive bonding, soldering and brazing are also reviewed. Importantly, joint design and testing are also topics dealt with by Fernie and Knowles.

The remainder of Section 8 looks at specific uses of ceramics in relatively aggressive environments. The chapter by Alary is a review of ceramic abrasives from an Industrial viewpoint. The abrasives market (including raw grits, abrasive tool bits and assembled abrasive tools) is of the order of 10 B€. Thus, manufacturing routes of abrasives are well developed as is the technology with over 50,000 patents being filed per annum. Alary discusses the properties required for abrasives and indicates how in addition to hardness, brittleness and friability are important. He also indicates how abrasive grits are classified by size. Alary describes typical fabrication processes for abrasive grits and draws attention to sol-gel processing which yields submicron grits and is a hot development topic. It is clearly pointed out in this chapter that the selection of an abrasive type, and indeed tool, requires a holistic approach with all application and abrasive property factors being taken into account. Ceramic materials for wear resistance are then reviewed by Hvizdoš. Having described the methods by which wear resistance is characterized, Hvizdoš discusses the wear properties of various oxide and non-oxide ceramic materials. More particularly, his chapter appraises the improvements in wear behavior, if the ceramic materials are reinforced with carbon nanostructures. These are primarily due to the development of a tribolayer affording a lower coefficient of friction. The formation of tribolayers is also important in the wear behavior of silicon nitride and sialons. Hvizdoš also discusses the wear behavior of silicon carbide, boron carbide, boride and high entropy ceramics. Lofaj and Mikula's chapter covers wear resistant ceramic coatings. Following an excellent explanation of tribology, wear mechanisms and erosion, Lofaj and Mikula discuss the importance of hardness to modulus (H/E) ratio as a "rule of thumb" indicator of wear resistance and how a composite approach to wear resistant coatings enables both hardness and modulus to be manipulated to obtain required H/E ratios. Lofaj and Mikula give an excellent and highly detailed review of coating methods as well as how nanostructured coatings can be developed on substrate surfaces. Concluding Section 8, is an important chapter by Jacobson and Opila on the oxidation and corrosion of non-oxide ceramics. This chapter deals in the main with silica forming materials (e.g., Si₃N₄, SiC) in oxygen, carbon dioxide and water vapor. The authors outline how water vapor accelerates oxidation rates of silica formers as it reacts with the silica to form non-protective volatile oxidation products. The adverse effects of sodium salts (often found in gas turbines) on the oxidation of silica formers is also discussed and attributed to the formation of low viscosity sodium silicate oxidation products. Jacobson and Opila also cover active oxidation of silica formers. Having looked at the oxidation of SiC-SiC composites, the chapter addresses the state of development of protective coatings; outlining their requirements and indicating some environmental barriers of use. The chapter concludes by addressing the oxidation of ultra-high temperature ceramics.

Ceramic Matrix Composites With Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior

Gilbert Fantozzi, University of Lyon, National Institute of Applied Sciences of Lyon, Materials: Engineering and Science (MATEIS), French National Centre for Scientific Research, Villeurbanne, France

Jérôme Chevalier, University of Lyon, National Institute of Applied Sciences of Lyon, MATEIS, Villeurbanne, France

Introduction

The main goal of ceramic matrix composites is to obtain ceramic-based materials with improved mechanical properties, especially toughness and/or strength and creep resistance. For this purpose, several reinforcement mechanisms can be used (Fantozzi and Chevalier, 2001) including phase transformation, microcracking, crack deflection, crack bridging, and fiber or whisker reinforcement.

These mechanisms will first be briefly presented. Then the application of these mechanisms on particle, whisker, carbon nanotube, graphene, and platelet-reinforced composites will be described.

General Background on Reinforcement Mechanisms in Ceramics

Transformation Toughening

Increases in strength and toughness can be obtained in ceramics that undergo a stress-induced transformation (Green *et al.*, 1989). The case of ceramics containing zirconia particles that present a tetragonal to monoclinic phase transformation is the most spectacular. By using an addition of Y_2O_3 , CeO_2 – other ions or even with the presence of a surrounding matrix with different thermomechanical properties (e.g., alumina) – zirconia can be kept in a metastable tetragonal-solid solution at room temperature. Under the effect of an applied stress, a martensitic tetragonal (t) to monoclinic (m) transformation may take place in the vicinity of the crack, which is associated with a volume increase and a shear strain that impede the crack opening and therefore lead to an increase of toughness. This increase is given by (Evans, 1984):

$$\Delta K_c^t = \frac{\eta e^T V h^{1/2}}{(1 - \nu)} \quad (1)$$

where η is a factor depending on the shape of the transformation zone around the crack, h its width, E the effective Young's modulus of the material, V the volume fraction of transformed particles, e^T the unconstrained transformation strain, and ν is Poisson's ratio.

The zone width and the volume fraction of transformable particles depend on the microstructure and especially on the grain size of the material and the dopant (e.g., Y_2O_3 or CeO_2) content, via the critical stress for transformation, σ_c . The higher the grain size (or the lower the dopant content) is, the lower is σ_c , thus the higher the volume fraction of transformed particles; however, when the grain size becomes higher than a critical size, d_c , spontaneous transformation occurs upon cooling and most grains are already transformed before crack propagation. There is therefore an optimum grain size/dopant content/zirconia content in the composite, for which transformation toughening is the most efficient.

Microcracking

When the size of the particles is greater than the critical size d_c , microcracking arises, which leads to a decrease in the strength of the material (Evans, 1984). However, if the particle size is smaller than the critical size, microcracks need additional stress to be induced that can be provided by the applied load. For efficient reinforcement, the microcracking must be confined in a process zone in front of the crack tip. The particle size must be as close as possible to the critical size to induce significant toughening, while preserving strength.

Crack Deflection

Cracks can be deviated either by the stress fields present around particles or by hard particles of higher resistance. This mechanism leads to a nonplanar crack, subjected to a mixed fracture mode. The analysis has been carried out for spherical, rod, and disc shaped particles for isotropic composite materials (Evans, 1984). In the case of discs and rods, the influence of the aspect ratio has been investigated. High deflection and therefore high toughening are obtained with rods with a high aspect ratio for a volume fraction of about 10%–20%.

This analysis has also been extended to the case of rods randomly oriented in planes in order to simulate transverse isotropic whisker-like composites. A more significant reinforcement can be obtained by crack deflection for this more specific case.

Crack Bridging

Such a reinforcement occurs when a crack meets a reinforcement particle without breaking it. The unbroken ligament exerts a bridging stress on the crack surfaces that counteracts the crack opening and thus reduces the stress intensity factor (Becher and Rose, 1994).

The toughening reinforcement is given by:

$$\Delta K_c^b = 2 \left(\frac{V_f \sigma \mu u_c}{1 - \nu} \right)^{1/2} \quad (2)$$

where V_f is the volume fraction of ligaments, σ the closing stress applied to the ligaments, μ the shear modulus, and u_c the crack opening at the end of the bridging zone.

The reinforcement depends on ligament density and the stress exerted by the ligaments, as well as on the crack opening. The reinforcement must exhibit a high strength in order to exert the highest possible stress and must be of large dimension in order to bridge over a large crack opening.

Whisker (Short Fiber, Carbon Nanotube, or Graphene) Reinforcement

The analysis of toughening by whisker reinforcement has been reviewed by Becher and Rose (1994). They consider uniaxially aligned whiskers. The analysis of reinforcement by whiskers is close to that developed for crack bridging. However, debonding of the whisker–matrix interface, and consequent friction at the interface, are generally taken into account. When whisker–matrix interface debonding occurs, the bridging stress supported by the whisker is reduced and a large bridging zone appears.

The energy dissipated by friction is given by:

$$\Delta G^f = \frac{V_f (\sigma_f^w)^3 r}{GE^w \tau_0} \quad (3)$$

where σ^w , E^w , r , and V_f are, respectively, the strength, the Young's modulus, the radius, and the volume fraction of whiskers, and τ_0 the interfacial shear stress.

The fracture energy increases as the interfacial shear stress decreases (i.e., when more interface debonding occurs). Furthermore, after whisker failure, whisker pull-out can contribute to additional toughening.

In the case of short fibers, carbon nanotubes, or graphenes, the same dependence of the fracture energy is observed: Low fiber (or reinforcement)–matrix adhesion and high fiber (or reinforcement) strength are needed in order to obtain matrix microcracking and fiber (or reinforcement) pull-out with friction and energy absorption.

Mechanical Properties of Zirconia-Toughened Composites

As shown in Section "Transformation Toughening", the fracture toughness increase is due to the $t \rightarrow m$ transformation of zirconia particles and needs the retention of $t\text{-ZrO}_2$ after sintering and cooling. This retention can be obtained by using several types of microstructures (Claussen, 1984). In all cases, the grain size of zirconia particles must be lower than the critical size d_c required for the spontaneous $t \rightarrow m$ without any stress, but sufficient enough to transform under stresses. Zirconia can be found in the form of tetragonal zirconia polycrystal (TZP) stabilized in the tetragonal symmetry by an addition of different oxides (e.g., cerium (Ce-TZP) or yttrium (Y-TZP) oxides). Zirconia can also exist in the form of tetragonal precipitates in a cubic matrix. An example is that of magnesia partially stabilized zirconia (Mg-PSZ), which is a composite structure of two phases (tetragonal precipitates in a cubic matrix). Zirconia particles can also be dispersed in a ceramic matrix other than ZrO_2 : These materials are called ZrO_2 -dispersed ceramics. An example of such a composite is ZrO_2 -toughened alumina (ZTA) of which a microstructure is shown in Fig. 1.

Effect of Size and Amount of Zirconia Particles on Toughening

Toughness improvement is related to the tetragonal particle size. In the case of partially stabilized zirconia (PSZ) the precipitate size depends on the annealing (sometimes referred as 'aging') conditions after sintering and solution treatment. A dramatic drop-off in toughness occurs when the precipitate size is just above the critical size d_c : the $t \rightarrow m$ transformation becomes spontaneous during cooling and the amount of tetragonal precipitates available for transformation decreases. Spontaneous transformation during cooling, especially if generalized to the entire composite, has to be avoided. Fig. 1 represents a ZTA composite where the zirconia grain size has been optimized in size (below d_c but above a certain size to induce transformation under stress at the crack tip) and distribution (as narrow as possible) in order to obtain the largest amount of transformation toughening (Chevalier et al., 2000).

Eq. (1) predicts that the toughness increment due to the $t \rightarrow m$ transformation depends on the volume fraction of transforming particles. This is actually observed (Becher and Rose, 1994) when care is taken to control the tetragonal particles content. If during processing, monoclinic particles or stable (nontransforming) particles are obtained, the transformation toughening contribution decreases. Hence, fracture toughness presents a maximum with increasing volume fraction of zirconia particles. The maximum occurs at higher volume fraction with smaller particle size. This behavior is due to local tensile thermal stresses that provoke

Fig. 1 Microstructure of a zirconia (10 vol%)-toughened alumina. Zirconia appears as the bright phase in back-scattered scanning electron microscope observation. From Encyclopedia of Materials: Science and Technology, Elsevier, 2001.

Table 1 Fracture energy of ZrO₂-toughened alumina ceramics

Abbreviation: PS, pressureless sintered, HP, hot-pressed.

spontaneous transformation of the zirconia particles during cooling, decreasing the tetragonal phase content. Maximum toughness occurs for a volume fraction of particles corresponding to thermal stresses (that increase with the volume fraction of ZrO₂) reaching the critical stress σ_c . In this case, another contribution to toughening due to ZrO₂ particles that have spontaneously transformed is microcracking in the stress field around the monoclinic particles. Fracture energy (G_c) values for different pressureless sintered (PS) or hot-pressed (HP) ZTA compositions have been measured (Fantozzi and Orange, 1986; Table 1). For PS composites, G_c is nearly constant up to 15 vol% ZrO₂ whereas, for HP materials, G_c shows a maximum near 10 vol% ZrO₂.

The observed increase in G_c in PS materials and to 10% ZrO₂ in HP materials can be attributed mainly to the stress-induced transformation-toughening mechanism as indicated by the relative amount to tetragonal phase Qr and as predicted by Eq. (1).

Above 15 vol% pure ZrO₂, the relative amount of tetragonal phase is considerably reduced and microcracking toughening becomes the effective mechanism. However, the microcracking toughening is not as energy dissipative as transformation toughening, thus toughness is lower and strength is often affected. This latter effect is thus generally avoided in practical terms, and most of industrial zirconia-toughened ceramics rely on phase transformation during crack propagation.

Effect of Solute Content and Temperature

With stabilizing agent additions, the initial tetragonal phase content increases (Table 1), which is reflected by an increase of the critical size d_c . Consequently, the stress-induced phase transformation toughening effect becomes preponderant over microcracking toughening and the fracture energy increases up to 2 mol% Y₂O₃. For higher Y₂O₃ content, the critical stress σ_c required to initiate the transformation increases and the tetragonal phase becomes too stable to induce transformation toughening (G_c decreases).

Because the critical stress σ_c increases with yttria content and the thermal stresses augment with the volume fraction of ZrO₂, the volume fraction of particles corresponding to maximum toughness increases also as a function of yttria content.

Fig. 2 Crack velocity versus stress intensity factor K_I in alumina, zirconia (Y-tetragonal zirconia polycrystal) and ZrO_2 -toughened alumina (10 vol% ZrO_2). From Encyclopedia of Materials: Science and Technology, Elsevier, 2001.

Fracture toughness decreases as temperature increases, σ_c increases. The reinforcement becomes negligible when temperature reaches about 600°C, the critical temperature at which the $t \rightarrow m$ transformation is no longer effective.

When the preponderant toughening mechanism is microcracking (e.g., the composite A20Z without stabilizing addition, in Table 1), toughening becomes independent of temperature.

Zirconia particles have also been added to reinforce other ceramic matrices. The preceding general features can be applied; however, toughening mechanisms are more complex (Green *et al.*, 1989).

Creep and Fatigue Behaviors of Zirconia-Toughened Composites

The creep behavior of zirconia-reinforced ceramics has been described by Fantozzi *et al.* (2000). The addition of zirconia particles does not improve the creep resistance, creep being essentially controlled by grain boundary sliding (GBS) in the matrix.

The static fatigue behavior of ZTA composites was studied at room temperature (Chevalier *et al.*, 2000). Fig. 2 shows the slow crack growth behavior of a reinforced alumina under static loading. For comparison, the results obtained for alumina and yttria-stabilized polycrystalline tetragonal zirconia (3Y-TZP) are also included.

Crack propagation is controlled by stress corrosion by water at the crack tip. Clearly, the slow crack growth resistance is increased for the ZTA composite, because the overall $V-K_I$ (crack velocity versus stress intensity factor) curve is shifted toward high stress intensity factors for the composite. A threshold K_{I0} below which no propagation occurs is observed in the three ceramics. The threshold K_{I0} is higher for the alumina composite compared to alumina or TZP. This result is very significant (e.g., for bioceramics applications such as hip joints) where the resistance to slow crack growth is detrimental. This explains, in part (some other factors also play a role in the overall reliability of a component), why current femoral heads are often made of ZTA ceramics (e.g., Biolox Delta®) (Chevalier *et al.*, 2009).

Cyclic loading promotes crack growth rate and leads to a decrease of the threshold stress. The fatigue behavior can be described as stress corrosion propagation associated with toughening degradation (as shown by Chevalier *et al.*, 1999). Several toughening mechanisms can intervene (e.g., transformation toughening, bridging, microcracking). Similar observations have been made on PSZ composites by Dauskardt *et al.* (1990). Nevertheless, ZTA composites still offer a better cyclic resistance than alumina monoliths or even 3Y-TZP.

Properties of Whisker Composites

Whiskers (W) were among the first reinforcements proposed in ceramic composites to improve toughness by crack deflection and bridging. Being strongly anisotropic, different composite textures can be observed depending on the processing route used to produce the composite. The reduction of densification induced by the whiskers has led to the use of hot pressing (HP), which produces a microstructure in which the whiskers are randomly oriented within a plane. This is also the case when the slip-casting route is used. Isotropic bodies can be obtained by powder preparation followed with pressureless or hot isostatic pressing.

The structural anisotropy can be observed on the microstructure and by toughness and strength measurements. An increase of both toughness and strength of about 50% has been measured in $SiC(W)-Al_2O_3$ composites when the crack plane was perpendicular to the whisker plane (Becher and Wei, 1984). Whiskers have been incorporated in alumina, silicon nitride, and to a lesser extent in mullite, zirconia, glass, or other matrices (Bradley *et al.*, 1988).

Fig. 3 Fracture toughness and flexural strength of whisker-reinforced alumina as a function of whisker content. From Encyclopedia of Materials: Science and Technology, Elsevier, 2001.

SiC(W)–Alumina Composites

Spectacular reinforcements by whiskers have been obtained in the case of alumina, with concomitant increases of both toughness and strength (Fig. 3). Toughness values higher than $10 \text{ MPa m}^{1/2}$ have been recorded for 20–30 vol% whisker content. Such composites have been made with small diameter whiskers ($0.3\text{--}0.6 \mu\text{m}$). The achievement of a similar strengthening depends on the whisker dispersion in the matrix and on the densification of the composite. In order to reach theoretical density, the composites are generally hot pressed. Fig. 3 shows the evolution of both toughness and flexural strength of alumina matrix composites with the SiC(W) addition.

As predicted by Eq. (3), higher toughening is obtained with increasing whisker diameter, strength, and volume content, and with decreasing the frictional interfacial shear stress.

However, due to the thermal expansion mismatch of SiC and Al_2O_3 , a too large whisker diameter induces matrix microcracking, reducing strength. Optimum results have been obtained with whisker diameters lower than $1 \mu\text{m}$ (Fantozzi and Olagnon, 1993).

The main toughening mechanisms are crack deflection and crack bridging. Reinforcement is observed up to about 1000°C .

SiC(W)–Other Matrices Composites

Whiskers have been incorporated in silicon nitride, mullite, zirconia, and glass (Becher and Rose, 1994). In the case of a Si_3N_4 matrix, the results were disappointing: The reinforcement is less significant than for alumina. This is due to the different microstructures observed for Si_3N_4 : Equiaxed or elongated grains depending on the sintering conditions and sintering aids. Toughness values of about $10 \text{ MPa m}^{1/2}$ have been observed. For other matrices, the toughness increase is lower.

In order to improve toughness further, various toughening processes can be combined: Whisker reinforcement, transformation toughening, and matrix microstructural-grain size effect. Either additive or coupled contributions can be obtained and multiple toughening mechanisms provide significant increase in fracture resistance: Values of $10 \text{ MPa m}^{1/2}$ have been observed for mullite reinforced by 20 vol% of SiC(W) and 20 vol% of $t\text{-ZrO}_2$ and toughness higher than $13 \text{ MPa m}^{1/2}$ has been achieved for ZTA reinforced with 20 vol% of SiC(W).

Creep Behavior

Most creep studies of these materials have been performed on whisker-reinforced alumina but other matrices such as Si_3N_4 , ZrO_2 , and mullite have also been studied (Fantozzi *et al.*, 2000).

The creep rate of alumina is reduced by the additional SiC(W), as shown by Fig. 4. This decrease depends significantly on the whisker content, size, and shape, on the presence of densification additives, and on the matrix grain size. The steady state creep rates of the alumina composites are two orders of magnitude lower than that of monolithic alumina. GBS, accommodated by diffusion processes, is the dominant mechanism responsible for the creep behavior of the composites. The addition of whiskers limits GBS, the whiskers acting as hard intergranular particles. For high whisker content ($> 30 \text{ vol}\%$), creep resistance is degraded, creep cavitation being enhanced. Similar enhancement in creep resistance is observed for mullite. However, reinforced Si_3N_4 , ZTA, or ZrO_2 do not show improvement in creep resistance.

Particle- and Platelet-reinforced Composites

Under this classification, only particles or platelets experiencing no transformation are considered.

Fig. 4 Stress dependence of the steady creep rate in flexure of alumina (1) and 20 vol% SiC (W) composite (2) at 1473K. From Encyclopedia of Materials: Science and Technology, Elsevier, 2001.

The concept is similar to that of whisker composites, but with lower potential toughening. However, this type of composites has the advantage of being processed by conventional methods. The development of such composites was primarily focused on tribological applications with a double target: Improving both toughness and hardness.

The reinforcement of alumina by SiC, TiC, BN, and TiN; of silicon carbide by TiB₂, TiC, and AlN; and of silicon nitride by SiC and TiC has been investigated (Fantozzi and Olagnon, 1993).

The residual stress due to thermal mismatch is an important parameter controlling toughening. When the thermal expansion coefficient of particles is lower than that of the matrix, composites are likely to experience microcrack toughening whereas in the opposite case, toughening will be mostly due to crack particle interaction.

A good example of toughening by microcracking has been observed in SiC–Al₂O₃ composites: A maximum in toughness occurs as a function of the particle contents. Highest toughening is obtained with the smallest particles but a strength degradation is observed for large-sized particles, due to the formation of large cracks.

In the case of Si₃N₄ reinforced with SiC, the highest fracture energy has been obtained with the coarse particles, crack deflection being responsible for toughening without microcracking.

Thus no general law between the toughness and the particle size can be stated since values observed strongly depend on the toughening mechanism. The reinforcement by particles can lead to values of 5–6 MPa m^{1/2} for toughness.

SiC or Al₂O₃ platelets have been incorporated into Si₃N₄, alumina, mullite, and TZP matrices. Toughening is due to crack deflection and crack bridging, with some pull-out. In the case of Si₃N₄, spectacular toughening has been observed with 30% SiC platelets (14 MPa m^{1/2}), but this was accompanied by a strength reduction. A special mention must be made with regard to nanocomposites (Niihara, 1991). The reinforcing nanosized particles are either inter- or intragranular. Indeed, room-temperature and high-temperature strengths are significantly improved in nanocomposites, although fracture toughness is only modestly increased. The particles bridging and the decrease of flaw sizes could be the essential strengthening mechanisms.

The creep behavior of particle or platelet-reinforced composites has been studied for different matrices (alumina, mullite, Si₃N₄) (Fantozzi *et al.*, 2000). In the case of alumina composites, the increase of creep resistance is lower than that observed with the whisker composites (one order of magnitude). On the other hand, alumina/silicon carbide nanocomposites present an excellent creep resistance: The creep rate is reduced by two to three orders of magnitude in comparison with alumina. The SiC nanoparticles hinder GBS and provoke a large improvement in creep resistance.

Improvement of creep resistance in other matrices for particle or platelet composites is also observed but is generally low. However, excellent creep resistance is obtained for mullite–zirconia composites and Si₃N₄ composites.

Mechanical Properties of Carbon Nanotube- and Graphene-Reinforced-Based Ceramic Composites

Carbon nanotubes, and more recently graphene nanoplatelets or graphene oxide nanosheets, have attracted a lot of attention in the materials science community to improve targeted properties such as wear resistance, conductivity and above all mechanical resistance. Thanks to the exceptional mechanical properties (very high modulus and strength) and electrical conductivity of carbon

nanotubes (CNTs) and graphene, fabrication of ceramics reinforced with CNTs and graphene presents a great interest in order to obtain tough and electric conductive ceramic composites (Ahmad *et al.*, 2015; Markandan *et al.*, 2017; Porwal *et al.*, 2013). Graphene is an interesting alternative to CNTs because it exhibits a large specific surface area and a homogeneous distribution in the matrix. The two types of reinforcements will be successively considered. Note that other types of graphene-based materials can be considered, or even other platelet-like reinforcements (e.g., boron nitride nanosheets). The fundamental mechanisms of toughening are quite similar to the ones described below.

Carbon Nanotube-Reinforced Ceramic Composites

The majority of composites are reinforced by using multiwalled CNTs (MWCNTs) against single-walls CNTs (SWCNTs). A good homogeneous dispersion of CNTs within the matrix must be obtained. This is detailed, for example, by Ahmad *et al.* (2015). A homogeneous dispersion is obtained only for the low CNT concentration (<2 wt%), agglomeration being observed for higher concentration. Furthermore, CNTs hinder the densification during sintering and the CNT-reinforced ceramics are very often sintered with a pressure-assisted process like spark plasma sintering (SPS) or hot pressing (HP) in order to obtain high density and good mechanical properties. This also preserves the quality of the CNTs.

Many studies show that higher fracture toughness are obtained for CNT-reinforced ceramics with MWCNTs and lower CNT addition (<2 wt%). Some authors have found the same fracture toughness than the matrix whereas others have even observed a decrease of fracture toughness (Lamnini *et al.*, 2019; Bocanegra-Bernal *et al.*, 2016).

It must be noted that the fracture toughness is measured with different techniques such as indentation fracture (IF) or single-edge notch beam (SENB) and single-edge V-notch beam (SEVNB). The validity of different methods of measurement is always controversial but the SENB or SEVNB methods are generally considered as more consistent and accurate. However, IF should be considered (with care) for comparison and evolution purposes.

Regarding hardness, very often it decreases with the addition of NTCs. This decrease can be related to the density decrease, the agglomeration of CNTs or to the presence of soft phases along the grain boundaries (Shin *et al.*, 2018). An increase of hardness can be observed for the composites, which is attributed to the reduction of grain size.

Three typical examples of reinforcement by CNTs will be subsequently addressed.

The first one concerns the reinforcement of alumina matrix by SWCNTs (Shin *et al.*, 2018). A homogeneous dispersion of SWCNTs and nearly full densification were achieved by SPS. The variation of the elastic modulus is shown in Fig. 5: The elastic modulus decreases with increasing the CNT content. This decrease is linked to the density decrease. The evolution of hardness and IF toughness is described in Fig. 6. Although grain size is decreasing, the hardness decreases due to a decrease of the density and an agglomeration of CNTs. The fracture toughness is slightly increasing as a function of CNT content from 3.7 MPa m^{1/2} for monolithic alumina to 4.2 MPa m^{1/2} for 1 wt% SWCNT addition. The flexural strength measured by three-point bending test increases with increasing the CNT content except for 1 wt% due to the decrease in density and CNT agglomerates.

The toughening mechanisms occurring in the composites are crack deflection, crack branching, and crack bridging.

The second example corresponds to nanostructured high purity 3 mol% yttria-stabilized zirconia (3YSZ) reinforced by MWCNTs. Full-dense nanostructured composites (98%) without damage of NTCs (Mazaheri *et al.*, 2011) were processed by SPS

(the grain size is about 100 nm). No evidence of CNT damage and agglomeration can be observed up to 5 wt% CNT content. MWCNTs reduce grain growth because they pin grain boundaries.

Fig. 7(a) shows a scanning electron microscopy (SEM) image of a fracture surface of 3YSZ/5 wt% CNT. A homogeneous distribution of MWCNTs in nanostructured zirconia matrix is observed and CNT pull-out is apparent. The high resolution transmission electron microscopy (TEM) image shows clean interfaces between MWCNTs and zirconia grains (**Fig. 7(b)**). The evolution of the fracture toughness (measured by two methods IF and SEVNB) and Vickers hardness is shown in **Fig. 8** as a function of the MWCNT content. A significant increase of toughness with increasing CNT content and a slight increase of hardness are observed (**Fig. 8(a)**). To ensure that the reinforcement is not due to phase transformation toughening but is due to the effect of CNTs, it was verified that the stress-induced monoclinic phase decreases with the increase of CNT content due to the decreasing grain size. Thus the reinforcement can only be attributed to CNTs.

The toughening mechanisms frequently reported for the reinforcement are pull-out, crack deflection and crack bridging. **Fig. 9** shows the MWCNTs are stretched between crack faces of the indentation-induced crack with the occurrence of crack bridging, crack deflection and CNT pull-out (**Fig. 9(b)**).

Nanotubes are flexible and are not embedded within the matrix grains and are present especially along the grain boundaries. The length of emerging CNTs on the fracture surface is short (< 200 nm) and therefore the energy dissipation for debonding is negligible as suggested by [Mukhopadhyay et al. \(2010\)](#). Furthermore, as shown by **Fig. 7(b)**, a strong interface between CNT and matrix is observed that does not allow pull-out and that leads to a higher elastic modulus of the composites compared to the monolithic zirconia one.

A possible mechanism responsible for both toughening and strengthening is thus the uncoiling and stretching of NTCs producing crack bridging as shown by **Fig. 9(b)**, leading to fracture work and energy dissipation. It can be also noticed a pinning effect of CNTs that inhibit GBS and creep at high temperature.

The last example concerns the toughening of nanostructured MWCNT/SiC composites sintered by SPS without sintering additives ([Lanfant et al., 2019](#)). CNTs have a negative effect on the densification and leads to a decrease of grain size with

increasing CNT content. However, it is possible to achieve nanostructured composites with a relative density of 97% for 3 vol% of CNTs. A beneficial effect of CNTs on the mechanical properties is obtained. Vickers hardness was increased up to 2560 Hv (for 3 vol% of CNTs) instead of 2080 Hv for the SiC matrix. The evolution of fracture toughness estimated by IF as a function of CNT content is shown in Fig. 10. Up to 3.2 vol% of CNTs, a clear increase of toughness is observed and a toughness of 4 MPa m^{1/2} is reached. Then a small decrease is observed for CNT content higher than 3.2 vol%. The SEM observations of fracture surfaces

Fig. 11 Toughening mechanisms by graphene platelet in Si₃N₄ composites: Crack branching (a), crack bridging, (b) and pull-out (c). From Kvetkova, L., Duszova, A., Hvizdos, P., *et al.*, 2012. Fracture toughness and toughening mechanisms in graphene platelet reinforced Si₃N₄ composites. *Scripta Materiala* 66, 793–796.

show the bridging and the pull-out of CNTs, mechanisms improving toughness. For higher content than 3.2 vol%, toughness is decreasing due to the presence of CNT bundles in the composites.

In summary, CNTs allow to improve the mechanical behavior of CNT-reinforced ceramic composites, especially fracture toughness. Furthermore, CNTs can act as lubricant leading to wear resistant materials, decreasing the friction coefficient. They can also lead to conductive materials, which is positive for some applications as well as for electro-machining.

Graphene-Reinforced Ceramic Composites

Graphene presents similar electrical, mechanical, and thermal properties to CNTs (Ahmad *et al.*, 2015; Markandan *et al.*, 2017; Porwal *et al.*, 2013). Graphene exhibits a higher specific area and can be more easily dispersed into a matrix without formation of tangles compared to CNTs. Powder processing used for graphenes-reinforced ceramic composites is very similar to that used for CNTs, and the same sintering techniques with application of pressure are used.

Many authors have reported an improvement of mechanical properties of ceramics by addition of graphene. An example of increase of IF toughness of alumina with addition of reduced graphene oxide (RGO) is shown in Fig. 6: The fracture toughness increases up to 4.7 MPa m^{1/2} for 1 wt% RGO addition. The elastic modulus and hardness of RGO-reinforced composites are decreased with RGO addition, the relative density being slightly higher (Figs. 5 and 6). This decrease can be linked to the sliding feature and low elastic modulus of RGO.

The toughening mechanisms reported for the reinforcement by graphene are similar to mechanisms observed for CNTs: Pull-out, crack deflection, crack branching, and crack bridging.

Fig. 11 shows these different mechanisms observed by Kvetkova *et al.* (2012) in graphene platelet (GPL)-reinforced Si₃N₄ composites. The IF toughness of the composites is increased from 6.9 MPa m^{1/2} for the matrix up to 9.9 MPa m^{1/2} for a composite reinforced with 1 wt% GPL addition. Fig. 11(a) shows crack branching linked to the interaction of the propagating crack and smaller GPLs – with the occurrence of secondary cracks. Crack deflection is observed upon crack interaction with larger GPLs. Fig. 11(b) shows crack bridging by larger GPLs and Fig. 11(c) pull-out by a large GPL. It can be noticed that the energy required for the pull-out of graphene sheet is more important than for NTCs due to sheet wrapping and larger contact area between GPL and matrix grains. The interface nature plays a significant role in the toughening compared to CNTs.

Conclusion

Monolithic ceramics can be toughened with roughly equiaxed reinforcements primarily to increase toughness, strength, creep resistance, and fatigue behavior. A wide variety of approaches can be used to reinforce ceramics: Toughness values can be increased from 2–4 MPa m^{1/2} for monolithic ceramics to about 15 MPa m^{1/2} for composites with an optimized microstructure. Special care must be taken in terms of choice of compositions and processing, since there is generally a maximum in mechanical properties (corresponding to an optimum in terms of toughening) before a quite strong decrease occurs. In any case, good dispersion of the reinforcement is absolutely mandatory.

Processing and Microstructure of Al_2O_3 -SiC Nanocomposites

Al_2O_3 -SiC nanocomposites are produced using standard ceramic processing techniques. Matrix and second-phase powders are typically comilled in an organic medium to achieve a uniform dispersion of second phase throughout the matrix. After milling, the nanocomposite powder is dried and then densified using pressureless sintering or hot pressing. Relative to that of monolithic Al_2O_3 , densification in the nanocomposite is strongly inhibited by the presence of particles on grain boundaries, which reduce the rate of grain-boundary diffusion. As a result, the sintering conditions necessary to achieve full densification are strongly dependent on the amount of second phase, with the sintering temperature increasing significantly with the second-phase volume fraction. While monolithic Al_2O_3 can be pressureless sintered to near-theoretical density at 1400 °C, a temperature of 1775 °C is necessary for full densification in a nanocomposite of Al_2O_3 containing 5 vol.% SiC (Stearns *et al.*, 1992). In fact, no study has shown that full density can be achieved using pressureless sintering in a nanocomposite containing more than 5 vol.% SiC. The difficulties of densification in the nanocomposite can be alleviated by hot pressing. During hot pressing, an applied pressure increases the driving force for densification, allowing dense nanocomposites to be manufactured at lower temperatures (e.g., 1500 °C for 5 vol.% SiC) and with higher volume fractions of second phase (e.g., 20 vol.% SiC at a temperature of 1675 °C) (Stearns and Harmer, 1996).

The processing steps used to produce nanocomposites have a significant effect on their microstructures and properties. It is well known that the properties of the nanocomposite are strongly dependent on the second-phase dispersion (Stearns *et al.*, 1992). Specifically, a uniform dispersion of second phase is critical to obtaining superior properties in the nanocomposite relative to the monolith. Unfortunately, the spatial distribution of the second phase has been shown to be very sensitive to the processing conditions used, indicating that small changes in processing can lead to significant differences in the properties of the nanocomposite.

The microstructures of nanocomposites produced using the above technique are also strongly dependent on the amount of second phase present. In nanocomposites with a high volume fraction of second phase (>5 vol.%), matrix grains are equiaxed with a narrow size distribution, and second-phase particles are uniformly distributed among the matrix grains. An example of this type of microstructure (5 vol.% SiC in Al_2O_3) can be seen in Figure 1. On the contrary, in samples with a low volume fraction of second phase, the grain-size distribution of matrix grains may be significantly wider and in extreme cases, abnormal grains may be present.

As shown in Figure 1, second-phase particles in the nanocomposite are either located on grain boundaries (intergranular) or inside grains (intragranular). As will be discussed later, the location of particles with respect to grain boundaries plays the paramount role in the improvement of the properties of the nanocomposite over the monolith (Xu *et al.*, 1997). In particular, intragranular particles are believed to be responsible for the superior room-temperature properties of the nanocomposite, while the intergranular particles are believed to be responsible for its superior high-temperature properties. Intergranular particles also significantly increase the microstructural stability of the nanocomposite. The interaction of particles with grain boundaries strongly inhibits matrix grain growth which would normally take place at high temperatures. Figure 2 shows SiC particles inhibiting grain growth in the nanocomposite by pinning migrating grain boundaries. The relative proportions of intra- and intergranular particles is strongly related to the matrix grain size in the Al_2O_3 -SiC system, with the percentage of intergranular particles decreasing significantly with the grain size. For example, approximately 70% of particles are expected to be intergranular for a grain size of 1 μm , whereas 25% of particles are expected to be intergranular for a grain size of 5 μm (Stearns and Harmer, 1996).

Figure 1 Scanning-electron-microscope image of the microstructure of a Al_2O_3 -5 vol.% SiC nanocomposite showing the presence of both intergranular and intragranular particles.

Figure 2 Scanning-electron-microscope image of SiC particles (5 vol.%) inhibiting grain growth by pinning migrating Al₂O₃ grain boundaries.

Room-Temperature Properties of Al₂O₃-SiC Nanocomposites

The superior mechanical properties of Al₂O₃-SiC nanocomposites at room temperature were first shown by Niihara, who found that the addition of 5 vol.% of 300 nm SiC particles to Al₂O₃ increased the strength from 380 to 1100 MPa (Niihara and Nakahira, 1988). Furthermore, it was shown that a simple annealing treatment at 1300 °C for 1 hour in argon gas subsequently increased the strength of the nanocomposites to over 1500 MPa. Niihara reported that the addition of the SiC particles also resulted in a significant increase in the fracture toughness, from 3.8 to 4.7 MPam^{1/2}. The superior properties of Al₂O₃-SiC nanocomposites over monolithic Al₂O₃ have been confirmed by a number of researchers, although none of these improvements have been as dramatic as those reported by Niihara (Zhao *et al.*, 1993; Borsa *et al.*, 1995; Jang *et al.*, 1996).

While the superior properties of the nanocomposite are well documented, the mechanisms responsible for the improvement in properties are still unclear. Proposed strengthening and toughening mechanisms for the unannealed nanocomposite include the reduction in critical flaw size due to the development of intragranular particle-induced subgrain boundaries, the attraction of intergranular cracks into matrix grains by residual tensile hoop stresses which arise due to the large thermal-expansion mismatch between Al₂O₃ and SiC, and the formation of a surface layer of compressive stresses during machining. The subsequent increase in strength and toughness after annealing has been attributed to the healing of surface flaws and the retainment of machining-induced compressive surface stresses, both the result of a slower stress relaxation behavior in the nanocomposite (Thompson *et al.*, 1995).

In addition to having improved strength and toughness relative to monolithic Al₂O₃, Al₂O₃-SiC nanocomposites also have superior wear properties. The improved wear properties are the result of a change in fracture mode which occurs when the concentration of the SiC second phase is greater than ~4 vol.%. While monolithic Al₂O₃ exhibits predominantly intergranular fracture, the large thermal-expansion mismatch between Al₂O₃ and SiC results in an apparent strengthening of Al₂O₃ grain boundaries, causing the nanocomposite to fracture transgranularly. As a result, grains in Al₂O₃-SiC nanocomposites are worn away slowly, in contrast to monolithic Al₂O₃ where wear typically involves the removal of entire grains due to the relatively weak interface at grain boundaries. The effect of the change in fracture mode on the wear properties of the nanocomposite is dramatic. In one study, the wet erosive wear rate of a 5 vol.% SiC nanocomposite was measured to be one-third that of monolithic Al₂O₃ with the same grain size (Walker *et al.*, 1994). Furthermore, the lack of grain pullout in the nanocomposite allows a higher-quality surface finish to be prepared (and retained during wear) than is possible with monolithic Al₂O₃.

High-Temperature Properties of Al₂O₃-SiC Nanocomposites

In addition to its superior room-temperature properties, Al₂O₃-SiC nanocomposite also possesses superior high-temperature properties. The superior strength and toughness of the nanocomposite at room temperature are retained as high as 1000 °C (Niihara and Nakahira, 1988). Furthermore, studies have shown that at higher temperatures, the creep resistance of Al₂O₃ is increased significantly by the presence of SiC particles (Ohji *et al.*, 1995; Thompson *et al.*, 1997). As shown in Figure 3, the creep rate of Al₂O₃ containing 5 vol.% SiC (150 nm) is 2–3 orders of magnitude lower than that of monolithic Al₂O₃ at temperatures as high as 1300 °C. In addition, the creep life of the nanocomposite is more than an order of magnitude longer than in the monolith. Unfortunately, the failure strain of the nanocomposite is lower than that of Al₂O₃ due to the nucleation of cavities at intergranular particles. The improved creep resistance of Al₂O₃-SiC has been attributed to a number of mechanisms. These mechanisms include a reduction in the rate of grain-boundary diffusion due to the presence of intergranular particles; an inhibition of shape-accommodation processes necessary for creep to occur, such as grain-boundary sliding and migration; and a reduction of the intrinsic grain-boundary diffusivity of Al₂O₃ by silicon cation contamination. The dominant mechanism responsible for the improved creep behavior of the nanocomposite is unknown.

Figure 3 Plot of creep strain rate as a function of temperature for monolithic Al_2O_3 and Al_2O_3 -5 vol.% SiC nanocomposites (after Thompson *et al.*, 1997).

Concluding Remarks

Ceramic nanocomposites are relatively new materials which appear to have promise. In particular, Al_2O_3 containing nano-sized SiC second-phase particles has been shown to possess both room- and high-temperature properties which are superior to monolithic Al_2O_3 . These properties, which include higher strength and toughness, increased wear resistance, lower creep rates at elevated temperatures, and excellent microstructural stability, make nanocomposites an attractive alternative to monolithic ceramics for many structural applications.

Introduction

Development of new materials with extreme mechanical, thermal and electrical properties is of technological interest. Silicon nitride based ceramics are well-known as low density materials with high strength and toughness, thus they are ideal candidates for several structural applications, even at high temperatures. By in-situ tailoring processes, the mechanical properties may be improved through the formation of tough interlocking microstructures (Shen *et al.*, 2002; Thompson, 2002). Depending on processing route, micro/nano or nano/nano type microstructures can be synthesized (Bhaduri and Bhaduri, 1998). Many recently developed preparation routes exist to produce ceramic matrix composites with superior technological characteristics (Papakonstantinou *et al.*, 2001). Although diamond and graphite have been well known for centuries, nanosized allotropes of carbon such as fullerenes, nanotubes and lastly graphene have been only discovered recently. Monolayer graphene is a one atom thick sheet composed of hexagonal structures of carbon atoms, however graphene samples with two or more layers are also being investigated with equal interest. This two dimensional material is characterized by exceptional electrical, mechanical and thermal properties (Balandin *et al.*, 2008; Geim and Novoselov, 2007; Rao *et al.*, 2009; Segal, 2009; Soldano *et al.*, 2010). Researchers have proved that electrons can move ballistically in graphene layers with a mobility exceeding $200,000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Moreover, graphene has unique thermal conductivities (up to $5300 \text{ W m}^{-1} \text{ K}^{-1}$) and it has superior mechanical properties with a Young's modulus of approximately 1.0 TPa. Interestingly, despite their non-perfect structure, even suspended graphene oxide sheets retain a Young's modulus of almost 0.25 TPa. Therefore, it is expected that the addition of graphene based materials will significantly improve the properties of different matrices, such as polymer, metal and ceramic (Ramanathan *et al.*, 2008).

In the last few years there are increasing numbers of reports on the use of graphene in ceramics. Fan *et al.* (2010) have prepared graphene nanosheet reinforced alumina matrix composites. The electrical conductivity of that composite outperforms the conductivity of the Al_2O_3 /carbon nanotube composites. The research on ceramic composites with incorporated carbon-based fillers has mainly focused on carbon nanotubes (CNTs) at the beginning of the 21st century. In the first decade, various CNT-reinforced ceramic systems have been developed and improved properties of these composite materials have been reported in a large number of works. It has been reported that a significant increase in bending strength and fracture toughness has been achieved in CNT reinforced alumina matrix composites (Ahmad *et al.*, 2010; Xia *et al.*, 2004; Yamamoto *et al.*, 2008; Zhan *et al.*, 2003). On the contrary, other researchers have not found such increases in toughness, but have noted significantly improved contact-damage resistance for these composites (Wang *et al.*, 2004). Considerable increases in electrical conductivity have been achieved in carbon nanofibers-zirconia composites (Dusza *et al.*, 2009) and CNT reinforced silicon nitride matrix composites (Gonzalez-Julian *et al.*, 2011; Tatami *et al.*, 2005; Yoshio *et al.*, 2011). In addition, the carbon nanotubes can influence the thermal conductivity (Corral *et al.*, 2011) and the friction coefficient (Hvizdos *et al.*, 2011) of silicon nitride composites. It has also been shown that with carbon nanostructure (CNT, graphene) incorporation into ceramic matrices, new emerging technologies can be foreseen and established (Fényi *et al.*, 2008a; Maleka *et al.*, 2011; Ramirez *et al.*, 2011; Balázs, 2012).

From an electrical point of view, ceramic matrix materials (e.g., alumina, silicon nitride) are regarded as typically insulator materials. The carbon additives, such as carbon nanotube (CNT) and graphene (GR) can drastically change the electric properties of the composites (Balázs *et al.*, 2005a; Kónya *et al.*, 2002; McLachlan *et al.*, 1990; Thostenson *et al.*, 2001). Analysis of the resistance measurements, changes in electric nature as a function of the type and concentration of the carbon additive can be determined. Indeed, carbon addition influenced mainly the electric properties, e.g., insulator – conductor transition (Fényi *et al.*, 2008b).

Definition of Composite, Nanocomposite Material

A composite consists of at least two different materials with significantly different physical or chemical properties. The definition of nanocomposite material has broadened significantly to encompass a large variety of systems such as one-dimensional, two-dimensional, three-dimensional and amorphous materials, made of distinctly dissimilar components and mixed at the nanometer scale (Niihara, 1991). Reducing the sizes of structural features in materials leads to a significant increase in the portion of surface/interface atoms. The surface/interface energies essentially control the properties of a solid, thus interfaces provide a means of introducing non-homogeneity into a material. This non-homogeneity can result in significant modification to both thermal and mechanical properties of the composites. Thus, selective mixing of materials with a highly tailored morphology with high percentage of interface area, leads to composite materials with enhanced properties.

The properties of composite materials depend not only on the properties of their individual components, but also on their morphology and interfacial characteristics. Nanocomposites find their use in various applications because of the improvements in the properties over the simpler structures. Some advantages can be summarized as:

Fig. 1 Schematic diagram of silicon nitride. (a) α - Si_3N_4 , (b) β - Si_3N_4 .

- (1) Improved mechanical properties e.g., strength, modulus and dimensional stability.
- (2) Decreased permeability to gases, water and hydrocarbons.
- (3) Higher thermal stability and heat distortion temperatures.
- (4) Higher flame retardancy and reduced smoke emissions.
- (5) Higher chemical resistance.
- (6) Smoother surface appearance.
- (7) Higher electrical conductivity.

Starting Materials for Composite Preparation

Silicon Nitride (Si_3N_4)

Two crystalline modifications of silicon nitride are widely known and researched. **Fig. 1** shows a schematic diagram of the α - Si_3N_4 (**Fig. 1(a)**) and β - Si_3N_4 (**Fig. 1(b)**) phases. Both structures are made up of tetrahedra containing one silicon atom in the center and four nitrogen atoms at the corners. They are covalently bonded to each other. The crystal structure of the α and β phases is hexagonal. The difference between the a unit cell parameter is not very significant (for α - Si_3N_4 $a = 7.818 \text{ \AA}$, and for β - Si_3N_4 $a = 7.608 \text{ \AA}$) (Villars and Calvert, 1986). However, along the longitudinal axis (c -axis), the unit cell c dimension of the α -phase ($5.591 \text{ \AA}$) is about twice that of the β -phase ($2.911 \text{ \AA}$) (Villars and Calvert, 1986).

α - Si_3N_4 ceramics typically have an equiaxed structure. In contrast, β - Si_3N_4 ceramics have elongated, needle-shaped grains which are less hard than α - Si_3N_4 . Due to its rod-like shape, the material may have an inhibitory effect on crack propagation, and thus the material containing β - Si_3N_4 has a higher toughness than the material containing only α - Si_3N_4 . The alpha and beta phases are similar in that some of the Si atoms can be replaced by Al and some of the N atoms can be replaced by O, this material is called SiALON (Hampshire *et al.*, 1978).

During the sintering of Si_3N_4 ceramics, oxide additives react with silica present on the Si_3N_4 particles to form an oxynitride liquid. The α silicon nitride dissolves in the sintering liquid and is transformed into the β form. The $\alpha \rightarrow \beta$ transformation features seem to be independent of the amount of additive. Ruzjukevics and Ishizaki (1993) reported $\alpha \rightarrow \beta$ transformation at about 1750°C during sintering of α - Si_3N_4 with 3%, 5% and 7% YAlO_3 as sintering aid. Yang *et al.* (2000) found complete transformation during sintering at about 1700°C for different compositions ($2.5\% \text{ Y}_2\text{O}_3 + 1.0\% \text{ Al}_2\text{O}_3$, $5.0\% \text{ Y}_2\text{O}_3 + 2.0\% \text{ Al}_2\text{O}_3$ and $10.0\% \text{ Y}_2\text{O}_3 + 4.0\% \text{ Al}_2\text{O}_3$) of the same additive system studied by Lee *et al.* (1990). Similar results have been found for various amounts of the same additive system (Hampshire and Jack, 1981). Hampshire and Jack (1981) reported a phase transformation activation energy in the presence of a liquid phase close to 405 kJ mol^{-1} , which is near the Si–N bond energy (435 kJ mol^{-1}). Suematsu *et al.* (1997) reported 500 kJ mol^{-1} for the phase transformation activation energy in a ceramic doped with Y_2O_3 and MgO. When the phase transformation accompanies densification and/or grain growth, the identification of the activation energy with specific kinetic processes is not easy, since there are various concurrent phenomena taking place.

Carbon Nanotubes (CNTs)

It is known that the carbon atoms of a single (graphene) sheet of graphite form a planar honeycomb lattice, in which each atom is connected through a strong chemical bond to three neighboring atoms. Because of these strong bonds, the basal-plane elastic modulus of graphite is one of the largest of any known material. The high elastic modulus, tensile strength, electrical and thermal conductivity of carbon nanotubes make them very attractive for ceramic-based composite applications. There are two main types of carbon nanotubes (CNTs): single-wall carbon nanotubes (SWCNTs) (**Fig. 2(a)**) and multi-wall carbon nanotubes (MWCNTs) (**Fig. 2(b)**). SWCNTs are characterized by high stiffness, high resistance to damage from physical forces. Three types of idealized carbon nanotube architectures exist depending on the folding versions of the basic graphene layer, which determines the arrangement of hexagons around the circumference: armchair, zigzag, or chiral. The electrical conductivity is highly sensitive to a slight change of helicity, which may cause a change of behavior between metallic and semiconducting states. There has been considerable practical interest in the

Fig. 2 Schematic illustration of carbon nanotube. (a) single-wall carbon nanotube (SWCNT), (b) multi-wall carbon nanotube (MWCNT).

conductivity of CNTs. Their conductivity has been observed to be a function of their chirality (degree of twist), as well as their diameter. Conductivity in MWCNTs is quite complex. Some types of “armchair”-structured CNTs appear to conduct better than other metallic CNTs (Arato and Balázs, 2008). Carbon nanotubes offer significant advantages over many existing materials due to their exceptional mechanical, electronic, and chemical properties, such as a specific electrical conductivity of $10^{-4} \Omega \text{ cm}$; a maximum current load of $10^{13} \text{ A cm}^{-2}$; a thermal conductivity of $2000\text{--}6000 \text{ W m}^{-1} \text{ K}^{-1}$; Young’s modulus of 1 TPa; and tensile strength of 30 GPa (Journet *et al.*, 1997; Thostenson *et al.*, 2001; Yu *et al.*, 2000).

Iijima (1991) developed a new, novel form of carbon, later named multi-walled carbon nanotube (MWCNT), by arc evaporation of graphite in the first instance. The discovered structure consisted of concentric graphene cylinders, and the diameter of each multi-walled tube was about 10 nm. Two other groups prepared single-wall carbon nanotubes (SWCNT), in which the diameter of each single-walled tube was 1 nm (Bethune *et al.*, 1993; Iijima and Ichlhashi, 1993). To date, several manufacturing technologies are available to prepare carbon nanotubes, such as high-pressure CO conversion (HiPCO) (Nikolaev *et al.*, 1999), pulsed-laser vaporization (PLV), chemical vapor deposition (CVD), and carbon arc synthesis (CA) (Huang *et al.*, 1998; Ren *et al.*, 1998, 1999). Promising approaches have been taken with CVD technologies, providing a method viable for industrial scale production of nanotubes. High purity CNT, both single-walled and multi-walled, can be obtained by reorganization of fragmented carbon fractions within a plasma environment created by arc discharge (Bethune *et al.*, 1993; Iijima and Ichlhashi, 1993; Journet *et al.*, 1997) or laser flash evaporation.

Graphene, Multilayered Graphene (MLG)

Generally, graphene is a one atom depth, two dimensional layer and usually exists as a film (Fig. 3(a)). Nevertheless, the gradually growing interest in graphene production has led to the creation of various graphene forms that can be used for unique purposes. These forms include chemical vapor deposited graphene (CVD), graphene oxide flakes (GO), reduced graphene oxide powders (rGO) graphene nanoplates (GNPs) and multilayer graphene powders (MLG) or few-layer graphene (FLG). Monolayer GO flakes can be obtained by chemical exfoliation of graphite (Hirata *et al.*, 2004). Graphene films are currently produced by chemical vapor deposition on metallic substrates. Chemical vapor deposition is an industrially relevant manufacturing method because it can produce large-area films that can be deposited onto a wide variety of substrates (Gall *et al.*, 1995, 1997; Novoselov *et al.*, 2004). The GO flakes are heavily functionalized by oxygen-containing groups such as epoxy, hydroxyl, carbonyl and carboxylic acid groups, and they form very stable dispersions in water. However, they are electrically insulating. On the other hand, GNPs are electrically conductive and predominantly hydrophobic. GNPs can be manufactured as a free-standing, powder-like material and

Fig. 3 Structure of graphene. (a) Schematic view of graphene single layer, (b) SEM images of MLG.

in large quantities and can act as a multifunctional additive. They are mostly obtained by exfoliation of graphite. For conciseness, we will focus on mainly the preparation and characterization of the MLGs and GNPs.

The different types of multilayer or few-layer graphene may be used as reinforcement materials for ceramic matrices. The quick and easy method for large-scale preparation of multilayer graphene (MLG) is the high efficiency attritor milling (**Fig. 3(b)**) (Kun *et al.*, 2011). For many industrial applications, using this process can be a simple and efficient way for graphene production.

The starting materials used in experiments were synthetic graphite powder and deionized water or ethanol without further purification. The graphite was milled in a high efficiency attritor mill (Union Process, type 01-HD/HDDM) equipped with zirconia disks and grinding media (diameter of 1 mm) in a 750 mL silicon nitride tank. The milling carried out with different rotation speeds (mild: 600 or intensive: 4000 rpm) for different times (5, 6 or 10 h). Finally, the milled suspension was dried and sieved through a filter with mesh size of 100 μm (Kun *et al.*, 2012).

Ceramic Matrix Composites (CMCs)

Ceramic Matrix Composites With Reinforcing Phase

The most common methods for processing nanocomposites are mechanical alloying powder processing methods followed by different sintering techniques (Samal and Smrutisikha, 2008). Mechanical alloying occurs as a result of repeated breaking up and joining of the component particles which can prepare highly metastable structures such as amorphous alloys and nanocomposite structures with high flexibility. Scaling up of synthesized materials to industrial quantities is easily achieved in this process, but purity and homogeneity of the structures produced remains a challenge. In addition to the erosion and agglomeration, high-energy milling can stimulate chemical reactions that are induced by the transfer of mechanical energy, which can influence the milling process and the properties of the product. Powder processing methods can also be used to fabricate ceramic matrices. The small diameter and large aspect ratio of the nanotubes could make it difficult to obtain a good distribution of the two phases prior to sintering or hot pressing. Using conventional milling techniques can improve the homogeneity of samples, especially with the use of low to moderate nanotube volume fractions.

Four main sintering methods are widely used: GPS (gas pressure sintering), HIP (hot isostatic pressing), HP (hot pressing) and SPS (spark plasma sintering). A discussion on the HIP and SPS techniques will be given in more detail. Tatami *et al.* (2005) prepared a Si_3N_4 composite by ball milling in ethanol (Tatami *et al.*, 2005; Yoshio *et al.*, 2011). Fine high-purity powders of Si_3N_4 , Y_2O_3 , Al_2O_3 , AlN , and TiO_2 were used as raw materials. The multiwall carbon nanotubes used in this study had diameters of

60 nm and lengths of 6 μm . CNTs and a dispersant were added to ethanol. Ball milling was carried out at 110 rpm for 48 h using 5 mm zirconia balls to mix the powders. The powder mixtures were obtained by evaporating the ethanol. 4 wt% paraffin and 2 wt% Bis(2-ethylhexyl) were added as the binder and lubricant, respectively, to make granules by sieving the mixed powder using a nylon mesh with openings of 250 μm . The granules were molded by uniaxial pressing at 50 MPa, followed by cold isostatic pressing at 200 MPa. The organic binder was eliminated at 500°C for 3 h at 4 L min^{-1} N_2 flow. After dewaxing, the green bodies were fired at 1700, 1750, and 1800°C for 2 h in 0.9 MPa N_2 using a gas pressure sintering (GPS) furnace. To complete the densification, the gas pressure sintered samples were subjected to hot isostatic pressing (HIP) at 1700°C for 1 h under 100 MPa N_2 .

These results showed that the relative density of the CNT dispersed Si_3N_4 ceramics was higher than 90% except for the sample containing less than 1 wt% of CNTs and fired at a temperature of 1800°C. It was confirmed that CNTs exist in the samples with a higher density. The pullout length of CNTs on the fracture surface of samples fired at higher temperatures was shorter because of the degradation of the CNTs. By TEM observation, CNTs were found to exist in the grain boundary in the Si_3N_4 ceramics, and their diameter was found to be almost the same as that of raw CNTs. Electrical conductivity was exhibited in the samples containing more than 1 wt% CNTs though the sample containing only 0.5 wt% CNTs was an insulator. The electrical conductivities of the samples increased with increase in the firing temperature, which was explained by the grain growth of $\beta\text{-Si}_3\text{N}_4$. The bending strength of the samples with 1 wt% of CNTs was as high as that of samples without CNTs. Thus, CNT-dispersed Si_3N_4 ceramics having both electrical conductivity and a higher bending strength were obtained by controlling the quantity of CNTs and the firing temperature.

Pasupuleti *et al.* (2008) prepared a Si_3N_4 composite by ball milling in polyethylene containers. 90 wt% micron sized silicon nitride and conventional 6 wt% Al_2O_3 , 4 wt% Y_2O_3 , and 1 wt% ZrO_2 (total of 11 wt%) sintering aids were used for sample preparation. A batch of CNT- Si_3N_4 composite was prepared with 1 wt% MWCNTs as nano-additions and with identical sintering aids as the base line material. Arc grown multi walled carbon nanotubes were selected for incorporation into silicon nitride. The powder batches were ball milled inside a polyethylene container for 24 h. The slurries were dried and sieved through a 325 mesh screen. The powders were placed inside a graphite die. Uniaxial hot-pressing was performed under a nitrogen atmosphere at 1750°C for 1 h. A pressure of 30 MPa was applied.

It was shown that CNT additions cause a refinement of the microstructure, leading to a finer grain size as well as increased acicularity of grains. Densification is not seriously impacted by the CNT additions. There is a slight loss of hardness but a substantial gain in toughness due to the CNTs. Silicon nitrides with CNT additions showed a classic toughening behavior with a sharp rise in the crack growth resistance with crack length followed by a plateau. Crack propagation paths through the microstructure show evidence of crack-path deflection as a toughening mechanism. Fracture surfaces show the presence of CNTs thus indicating crack-bridging and CNT pullout as toughening mechanisms. The hot-pressing conditions used in this study have clearly allowed a good proportion of the CNTs to survive and enhance the toughness and toughening behavior of this CNT-silicon nitride composite.

Corral *et al.* (2008) investigated the effect of SWNTs on the electrical and thermal properties of Si_3N_4 after densification using spark plasma sintering (SPS). All of the nanocomposite and monolith specimens were made from powders that were dispersed using colloidal processing methods followed by SPS. 90 wt% Si_3N_4 powders and 10 wt% sintering additives (Y_2O_3 , MgO and Al_2O_3) were used in sample preparation. Commercially available SWNTs in powder form and purified to less than 2-wt% residual metal catalyst were used as received. The nanocomposites made in this study each contain a mixture of 1-, 2-, and 6-vol% well-dispersed single and bundled SWNTs. A cationic surfactant, cetyltrimethylammonium bromide (CTAB) was used as a dispersant throughout this study. They used SPS to densify nanocomposites using a maximum pulse current of 5000 A and maximum pulse voltage of 10 V. The pulse cycle was 12 ms on and 2 ms off with a heating rate of 200°C min^{-1} . The temperature was monitored on the surface of the die wall using optical pyrometry. An external pressure of 25 kN was applied as the powders were heated inside a graphite die lined with graphite foil to prevent surface reactions between the powder and the inner die wall. A vacuum of 10^{-2} Torr was used and sintering occurred under vacuum.

The use of only 2 vol% SWNTs additions resulted in a decrease of the room temperature thermal conductivity by 62% compared to the monolith and increasing the addition to 6 vol% SWNTs transformed the insulating ceramic into a metallic electrical conductor (92 S m^{-1}). It was found that densification of the nanocomposites was inhibited with increasing SWNT concentration, however the phase transformation from α - to $\beta\text{-Si}_3\text{N}_4$ was not. After SPS, they found evidence of SWNT survival in addition to sintering induced defects detected by monitoring SWNT peak intensity ratios using Raman spectroscopy. Their results showed that by densifying by SPS, SWNTs can be used to effectively increase electrical conductivity and lower thermal conductivity of Si_3N_4 due to electrical transport enhancement and thermal scattering of phonons by SWNTs.

Gonzalez-Julian *et al.* (2011) studied the Si_3N_4 /MWCNTs composites prepared by SPS and containing 0.9–8.6 vol% MWCNTs. CVD synthesized MWCNTs of 30 nm diameter and 1–5 μm length were thoroughly mixed with Si_3N_4 plus liquid forming sintering additives, 2 wt% of Al_2O_3 and 5 wt% of Y_2O_3 . Compositions were spark plasma sintered at 1585°C for 5 min in vacuum (6 Pa), applying a pressure of 50 MPa.

A balance was observed between semiconductor and metallic-like conduction mechanisms, the proportions of which depend on both the temperature and the MWCNTs content. The metallic-type conduction was associated with charge transport along the nanotube shells whereas the semiconductor behavior is linked to hopping conduction across nanotube–nanotube contacts and across intrinsic defect clusters within the nanotubes separating metallic domains. When the MWCNTs network is close to the percolation threshold (0.9 vol% composite), inter-nanotubes hopping or tunneling mechanisms become the rate limiting steps for charge transport. Once this concentration was surpassed the contribution of defect clusters within nanotubes in the highly conductive paths competes with the above mechanism.

Fig. 4 Schematic illustration of starting powder mixtures.

Graphene is a favored additive reinforcing phase for ceramic matrix composite development. Nano-scaled graphene platelets of several desired size ranges (e.g., length and width of approximately 0.05–10 μm and thickness of approximately 1–10 nm) demonstrate exceptionally high thermal and electrical conductivity and an exceptional combination of mechanical properties. Typically there are three methods used for the preparation of graphene platelets: micromechanical exfoliation, epitaxial growth of graphene film and chemical processing (Bhuyan *et al.*, 2016). Kun *et al.* (2011, 2012) used the attritor milling of graphite powder for multilayered graphene preparation and its distribution in ceramic matrices. Recently, conducting ceramic composites were fabricated by the in-situ formation of graphene-like layers (Weibel *et al.*, 2018). In particular, an aluminosilicate/graphene composite with an in-plane conductivity of 700 S m^{-1} was obtained by carbonization of polyaniline layers (Capková *et al.*, 2014). Likewise, SiC/graphene composites with $\sigma \approx 100 \text{ S m}^{-1}$ (~ 6 orders of magnitude larger than monolithic SiC ceramics) were obtained by growing epitaxial multilayers of graphene in-situ at the SiC grain boundaries during the spark plasma sintering (SPS) process (Miranzo *et al.*, 2013). Recently a very interesting point raised by a new ceramic/graphene design is that graphene is not used as a conventional ‘reinforcement’ but rather to engineer a fine network of relatively weak interfaces that provide improved electrical conductivity and fracture resistance (Picot *et al.*, 2017). The response depends not only on the chemistry but also on the topology (roughness) of the interfaces at the nano-scale. These results underline the need to look at alternative approaches in the way we design and build practical composites using nanomaterials and that these approaches will need to integrate mechanical and functional response. The latter is probably the most interesting possibility opened by these new layered nanomaterials and a path to generate a step change in the field of structural, multifunctional materials.

Preparation of Carbon Nanotubes- and Graphene-Containing Ceramic Matrix Composites

Powder technology methods were used for these ceramic matrix composite preparations (Fig. 4). The ceramic starting powders were Si₃N₄ (SN-ESP, UBE, Japan), Al₂O₃ (A16, Alcoa, USA), and Y₂O₃ (grade C, H. C. Starck, Germany). For composite processing, multi-walled carbon nanotubes (MWCNTs) and multilayered graphene (MLG) were added into the base ceramic with different concentrations (Fig. 5) (Balázs *et al.*, 2003, 2005b, 2006, 2007).

A stable, applicable processing technology for CNT/ceramic composites has to control the homogeneous distribution of nanotubes during powder mixing and shaping and preserve their amount and topology in the course of heat treatments.

The homogeneity of a powder mixture can be significantly improved by using very intensive milling. A new attritor mill (01-HD/HDDM, Union Process, USA) is being used, which operates at a high speed of 4000 rpm. Milling for 3–5 h with this equipment significantly changed the size and morphology of the powder mixture constituents. Spark plasma sintering (next to flash sintering) is a technique that has been successful in the research on nanoceramics. It was observed that this method decreases the sintering temperature, impeding the degradation of nanotubes and the Oswald ripening (excess growth) of matrix particles/grains.

Hot isostatic pressing (HIP) was performed at 1700°C in high purity nitrogen atmosphere in an ABRA-made HIP apparatus and 20 MPa for 3 h. Gas pressure sintering (GPS) can be done in the same HIP apparatus. Several temperature-time runs were tested, with a high temperature of 1750°C and a nitrogen pressure of 1.5 MPa. Hot pressing (HP) was used at 1700°C, 50 MPa in nitrogen for 1 h.

The dimensions of specimens after full densification (and cutting, polishing) were $3.5 \times 5 \times 50 \text{ mm}$. Before mechanical testing, all surfaces of the samples were finely ground on a diamond wheel, and then the edges polished.

In the case of SPS methods, the ceramic powder can be annealed at lower temperatures and for much shorter times than in other sintering processes (e.g., hot pressing, hot isostatic pressing, and pressureless sintering) and allows the fabrication of fully dense ceramics and composites with a nanocrystalline microstructure.

A key factor of a stable processing technology is prevention of degradation of nanotubes during sintering. The temperature of conventional sintering procedures is rather high for silicon nitride ceramics (1700–1800°C). These high temperatures are disadvantageous because the size of nanograins increases, a part of carbon nanotubes transforms to graphite, and a certain amount of carbon is lost at the surface and via open pores. The main difference between SPS and hot pressing is the simultaneous application of a pulsed current in the former, which generates electrical discharges (Groza, 1998). The electrical discharges do not densify powders and therefore, additional energy is required to increase the final density. This extra energy may be mechanical due to the applied pressure and thermal energy generated by electrical discharge. Electrical current activation has been applied in the plasma assisted sintering (PAS) process – developed in Japan in the 1960s – followed by today’s widely used spark plasma sintering method (Groza, 1998). The principle of SPS is based on the application of a pulsed DC current through and around the specimen. Conduction along the die is important, but it basically represents ohmic heating.

Fig. 5 Schematic diagram of steps of ceramic matrix composite preparation.

Table 1 Summarized data of apparent densities of carbon nanotube and graphene added Si_3N_4 composites prepared by different sintering methods

Sintering method	Additive	GPS	HIP	SPS	HP
		density (g/cm^3)			
Carbon nanotube	0 wt%	3.15	3.19	3.23	3.41
	1 wt%	2.807	3.028	3.17	–
	3 wt%	2.653	2.752	3.23	–
	5 wt%	2.240	2.245	–	–
Graphene	1 wt%	2.78	2.84	3.19	3.36
	3 wt%	2.62	2.589	3.174	3.37
	5 wt%	–	2.49	2.71	3.42

Silicon nitride composites containing carbon nanotubes and graphene have been produced by spark plasma sintering in vacuum (Dr. Sinter 2050 SPS, FCT HP D10-SD) (Balázsi *et al.*, 2005b, 2013). The powder precursors were loaded in cylindrical carbon dies with an inner diameter of 10 mm. The samples were heated via a pulsed DC current that assured $100^\circ\text{C}/\text{min}$ heating rate for all of the experiments. The temperature was automatically raised to 600°C over a period of 3 min, and from this point onward it was monitored and regulated by an optical pyrometer focused on the surface of the die. A uniaxial pressure of either 50 MPa or 100 MPa was applied from the start to the end of the sintering cycle. Short holding times were applied, from 3 to 5 min. The setup allows a cooling rate of about $400^\circ\text{C}/\text{min}$ in the temperature range $1650\text{--}1000^\circ\text{C}$.

Structure of CNTs- and Graphene-Containing Ceramic Matrix Composites

The selection of the ceramic matrix and amount of the reinforcing phase is a fundamental step. Thus, the Si_3N_4 matrix, which is more dense, is responsible for the mechanical strength of the final sintered composite, whereas the secondary reinforcing phase (carbon nanotube, graphene) determines the toughness and work of fracture. These non-oxide materials usually have much higher fusion temperatures than the matrix and do not dissolve in the liquid present during sintering. This means that the addition of any sort of nanoparticle/nanotube carbon phase is likely to significantly decrease the rate of sintering (Table 1).

A plausible explanation of this effect is to suppose that the added carbon phase located between ceramic particles hinders the generation and growth of interparticle contacts. Microstructural observations have confirmed that the carbon reinforcing phase has been located in pores between grains of the ceramic matrix, independent of sintering method (Figs. 6 and 7).

The $\text{Si}_3\text{N}_4/\text{MWCNT}$ composites studied consisted of Si_3N_4 grains with average size $300\text{--}500$ nm and multi-wall carbon nanotubes with diameter around 20 nm and lengths of a few microns (Fig. 6). For the three different densification processes, GPS, HIP, SPS, there is evidence for the presence of MWCNTs after sintering (Balázsi *et al.*, 2003, 2005a, 2013). The short sintering time with low pressure resulted in residual porosity in the Si_3N_4 composite. Web-like connected MWCNTs can be found in some areas, but

Fig. 6 Structural observation of $\text{Si}_3\text{N}_4/3$ wt% MWCNTs sintered by different methods. (a) GPS, (b) HIP, (c) SPS.

individual MWCNTs, properly attached to Si_3N_4 surfaces can also be observed (Fig. 6(a)). The ceramic grains along with the attached CNTs can be observed in the fracture surface of the HIP sintered composite (Fig. 6(b)). The ten times higher pressure and longer sintering time decreased the porosity and increased the density of the composite (Table 1). SPS can enhance the sinterability of Si_3N_4 producing dense materials with controlled grain growth. In SPS sintered composites, higher density was achieved (Table 1) with Si_3N_4 grains of average size 500 nm and MWCNT agglomerations between the ceramic grains (Fig. 6(c)) were observed.

In the case of graphene addition, various sintering methods such as hot pressing (HP), HIP and SPS may be used for sintering of final composites (Kun *et al.*, 2012; Balázs *et al.*, 2017; Tapasztó *et al.*, 2016).

One of the problematic issues of composite preparation is to improve the homogeneity of the dispersion of reinforcing phases (Fig. 8). Increasing milling time and ultrasonic agitation of powder mixtures can solve this problem. Highly efficient milling processes have a

Fig. 7 Structural observation of $\text{Si}_3\text{N}_4/3 \text{ wt\% MLGs}$ sintered by different methods. (a) HP, (b) HIP, (c) SPS.

Fig. 8 High resolution TEM images of sintered Si_3N_4 composites. (a) with MWCNTs, (b) with MLG additive.

double effect on structure; homogenization of the base powders and size reduction. In the case of Si_3N_4 composites containing MWCNT (**Fig. 8(a)**) or MLG (**Fig. 8(b)**), some structural defects after milling and sintering were observed (Kun *et al.*, 2012).

On the other hand, phase transformation of final composites occurred during the sintering process. The type of sintering, holding time and pressure have an effect on the α - Si_3N_4 matrix. The α - Si_3N_4 particles dissolved in the existing liquid phase and subsequently new β - Si_3N_4 nuclei were formed (Peng *et al.*, 2009). The higher carbon nanotube and graphene content may block the total phase transformation of Si_3N_4 (**Fig. 9**). The liquid phase is needed for the α - β phase transformation, which occurs by the dissolution of fine α -phase starting powder and subsequent precipitation of the β -phase (Riley, 2004). Sintering additives (mainly oxides) need to be added to assist the densification process through "liquid phase sintering" (Krstic and Krstic, 2012). In the case of Si_3N_4 , the best known system is a combination of Y_2O_3 and Al_2O_3 (Krstic and Krstic, 2012).

The phase transformations that may occur during processing of ceramic matrix composites are shown in **Fig. 9**. Phase analysis of composites revealed that the transformation α to β - Si_3N_4 was completed after HIP and HP sintering, where mainly the main lines of β - Si_3N_4 can be observed (**Fig. 9(a)** and **(b)**). In the case of GPS or SPS the α to β - Si_3N_4 transformation is not finished, therefore the main lines of both α and β - Si_3N_4 may be observed after sintering (**Fig. 9(a)** and **(b)**). It is known that during sintering the oxide additives react with oxidized surface layers on silicon nitride powders to form an eutectic liquid at high temperature. As a concurrent process by increasing the holding time of sintering the α to β - Si_3N_4 transformation is beginning, it is also known that the SPS is working with enhanced electrical field, rapid heating and very short sintering time. Due to these facts SPS can enhance the sinterability of Si_3N_4 producing dense materials with controlled grain growth (Belmonte *et al.*, 2010). The addition of the electrical conductive carbon phase to ceramic matrix modified the shrinkage behavior during sintering process. XRD measurements confirmed the ZrO_2 contamination from milling, where intensive milling at high speed (5000 rpm) was applied (**Fig. 9(a)** and **(b)**). In the literature there are several works where ZrO_2 is intentionally used as sintering aid (Pasupuleti *et al.*, 2008) or is added to matrix as a toughening agent (Sayyadi-Shahraki *et al.*, 2019). The line of (002) of carbon on XRD is supporting the results of microstructural investigations which show the presence of MWCNT (**Fig. 9(a)**) and MLG (**Fig. 9(b)**) after sintering.

Mechanical Properties of CNTs- and Graphene-Containing Ceramic Matrix Composites

Control of the mechanical properties of Si_3N_4 based composites is possible via the modification of their composition and processing conditions, knowing how the microstructure peculiarities can influence the mechanical behavior.

Fig. 9 Phase analysis of Si_3N_4 based composites. (a) MWCNT reinforce phase, MLG additive.

The determination of the hardness allows useful qualitative conclusions to be made regarding the mechanical properties of ceramic composites (Fig. 10(a)). It is one of the most economical characterization methods, since this can be carried out with little effort on small sintered sample.

Si_3N_4 ceramic matrix composites containing carbon nanotubes and graphene have hardness values between 11 and 19 GPa (Balázsi *et al.*, 2013, 2017; Kvetková *et al.*, 2012; Kovalčíková *et al.*, 2012) depending on the sintering method and amount of reinforcing phase. The highest hardness of the composite compared to the monolithic material is mainly dependent on the residual porosity that remains in the material after sintering and good homogenization of the reinforcing phase. Together with the porosity, clusters of MWCNTs or MLGs are characteristic processing defects present in the materials and have been presented and discussed in all of the other work dealing with similar composites. This indicates that there are some persistent difficulties in the preparation of defect free carbon nanotubes or graphene reinforced ceramic composites. Reducing such defects has the potential for the improvement of their functional and mechanical properties.

The MWCNTs and graphene play a favorable role by bridging the cracks, healing the crack openings as is proved by the crack morphology. In the case of Si_3N_4 /MWCNTs the width of crack openings are substantially smaller as compared to “pure” Si_3N_4 . On the other hand, the formation of MWCNT agglomerations (Fig. 6) and graphene agglomerations (Fig. 7) caused hardness to decrease by increasing porosity.

Fig. 10 Comparison of the mechanical properties of carbon nanotube and graphene added Si_3N_4 based composites prepared by various sintering technology. (a) hardness, (b) modulus of elasticity.

The modulus of elasticity (E) is one of the essential parameters in the study of advanced material mechanics. Its values for ceramic matrix composites with graphene addition showed higher values compared to composites with carbon nanotubes independent of the sintering method applied (Fig. 10(b)). In all cases, the reference Si_3N_4 without any second phase addition has the highest degree of densification related to the highest modulus value (Fig. 10(b)). It is known that the porosity due to reinforcing phase addition to the brittle matrix can have significant influence on mechanical properties. The better homogenization of graphene sheets caused lower porosities and finally higher strength values compared with agglomerated carbon nanotube reinforcing phases.

3-point bend strength data show a similar tendency, but higher values resulted for composites containing graphene compared with those containing carbon nanotubes (Fig. 11). All composites showed the same tendency. As a result of applying a higher pressure (20 MPa, in the case of HIP) a higher densification level, and a strength increase by 100% from an average level of 300 MPa to 600 MPa can be realized in the case of 1% CNT addition (Balázsi *et al.*, 2007).

Interestingly, contrary to CNTs, graphene addition has a beneficial role in the re-arrangement of grains during sintering at low nitrogen pressure (2 MPa, in the case of GPS) which at the end of sintering results in more dense structures with higher 3-point bending strengths as shown in Fig. 11(a).

In the case of Si_3N_4 , the reinforcing mechanism by adding second phase particles is introducing residual stresses induced by a different coefficient of thermal expansion (CTE) for the matrix (Gogotsi, 1994). The compressive residual stresses close cracks, while tensile residual stresses deflect stress. The residual stresses at the grain boundaries caused by different CTE between Si_3N_4 grains and grain boundary phase enhance crack deflection. The fracture toughness of Si_3N_4 ceramics increased almost linearly from

Fig. 11 Comparison of the 3-point bending strength of carbon nanotube and graphene added Si_3N_4 based composites prepared by various sintering technology.

Fig. 12 Crack deflection mechanism in graphene added Si_3N_4 ceramics.

4 to 5–6 $\text{MPa m}^{1/2}$ when a phase with higher CTE crystallizes at the grain boundaries (Peterson and Tien, 1995). Thus, the introduction of carbon nanotube or graphene reinforcing phase with higher CTE toughened the final Si_3N_4 composite. The basic mechanism of crack deflection in the Si_3N_4 composite containing graphene is shown schematically in Fig. 12. The indentation fracture toughness of the composites containing carbon nanotubes or graphene are significantly higher compared to the monolithic silicon nitride, with the highest value of 9.9 $\text{MPa m}^{1/2}$ for graphene reinforcing phase (Kvetková et al., 2012).

The observed differences in the mechanical properties of the samples prepared by different sintering methods have complex processes at their origin. Two factors could be named with important roles in the properties of the resulting composites:

- (1) The effect of different sintering methods on the phase transformation of the silicon nitride matrix, which is clearly reflected also in the final phase composition of the samples (SPS sintered samples mainly consist of $\alpha\text{-Si}_3\text{N}_4$, while HIP and HP sintered samples predominantly contain $\beta\text{-Si}_3\text{N}_4$ grains).
- (2) The effect of holding times at high temperatures on the structure (degradation) of the carbon reinforcing phase. It is known that both carbon nanotubes and graphene can be damaged during long exposures to high temperatures, whereupon their intrinsic mechanical properties can substantially decay. In this sense, the fast heating rates and short holding times of the SPS method are expected to better preserve the excellent mechanical properties of the filler phase.

Tribological Properties of Ceramic Matrix Composites

Significantly decreasing the friction coefficient is essential for reducing the losses in moving and rotating parts, while increasing the wear resistance improves the durability and lifetime of the components. In all such applications, Si_3N_4 materials will have to face the challenge of friction and wear damage.

Fig. 13 Friction coefficient of carbon nanotube and graphene added Si₃N₄ matrix composites.

Fig. 14 The specific conductivity of nanocomposites with different carbon additions and sintering method.

The friction behavior of the Si₃N₄ with different MWCNT and graphene additions tested under dry and wet conditions against SiC rings is shown in Fig. 13. For all investigated material combinations a decrease in friction coefficient is clearly visible with increasing reinforcing phase content.

In the case of HP and HIP sintered composites the morphological appearance of the worn surfaces showed that more stable and coherent tribofilms developed in the wear track. This provided better lubrication at the contact points under wet conditions. SPS sintering effectively improved the tribological performance of the Si₃N₄ composites by preserving the harder α -Si₃N₄ structure of the initial ceramic powder to a great extent.

The values for friction coefficients under wet conditions are in the range of 0.3–0.15 compared to between 0.45 and 0.83 under dry conditions (Balázs *et al.*, 2017; Hvizdoš *et al.*, 2012, 2013).

The lower friction coefficients during wet conditions may be related to the typical wear patterns for ceramic materials in water, i.e., tribochemical wear and some traces of surface microfracture and fatigue (Balázs *et al.*, 2017). It was demonstrated that graphene is preserved on the tribo-surface even after severe tribochemical wear. Consequently, at higher graphene content larger presence of multilayer graphene in the wear debris. As it was shown by (Belmonte *et al.*, 2013) the wear behavior in graphene added composites is controlled by the continuous supply during severe wear process of the exfoliated graphene flakes that are present in lubricating tribofilm well adhered to the surface.

Even though the SPS or HIP provided higher friction coefficients for reference samples the CNT or graphene beneficial role to decrease the friction coefficients during dry conditions might be observed on Fig. 11. By 5 wt% CNT or graphene addition, a 60% reduction in friction coefficient is achieved.

Carbon nanotubes and graphene contribute significantly to the decrease of friction coefficient. Increasing the amount of carbon phase has beneficial role showing lower frictional response of Si₃N₄ ceramic composites.

Electrical Conductivity of Ceramic Matrix Composites

Silicon nitride ceramics are insulators, with a specific conductivity of about $10^{-12} \text{ S m}^{-1}$. The examined composites can be grouped into insulator and conductor types as identified from four point DC resistance measurements. Si_3N_4 matrix composites can be considered as insulators because their resistance was not measurable (10 M Ω measurement limit). The percolation threshold was observed in composites with 3 wt% and 5 wt% MWCNT and 10 wt% for graphite (as reference) (Fényi *et al.*, 2008b). The specific conductivity range of the composites according to type, amounts of additives, sintering technique and type of ceramic matrix is shown in Fig. 14.

As for conductivity, the matrix does not take part in the charge transport, however it may modify the topology of the conductive phase. Composites with graphite additives (for comparison) have the worst electrical conductivity because of the size and shape of the mixed graphite grains (Fényi *et al.*, 2008a, 2009). In the case of lower values of MWCNT additives with better homogenization, the higher conductivity was observed (Fig. 14). In this structure, the nodules only few current paths maybe involved in conductivity process because of the nodulation of the MWCNTs. In case of higher MWCNT content, the homogenous distribution of reinforcing phase was not realized (Fényi *et al.*, 2008b), MWCNTs agglomerated in porosities and due to this, they are not connected (Fig. 6). Furthermore the crystallization and grain growth of β - Si_3N_4 grains may inhibit the bridging of MWCNTs (Fig. 6).

Conclusions

Silicon nitride (Si_3N_4) based ceramics are well-known as low density materials with high strength and toughness. Silicon nitride, known as a typical dielectric material, is an ideal candidate for several structural applications, even at high temperatures. The addition of graphene or carbon nanotubes to silicon nitride to create ceramic nanocomposites gives rise to promising applications in a wide range of fields such as electronics, biomedical aids, membranes, flexible wearable sensors and actuators. This chapter shows how the use of different reinforcing phases and sintering methods affects microstructure and as a result, mechanical properties, electrical conductivity and friction coefficients of the final silicon nitride nanocomposites.

The main important conclusions that can be drawn are:

- (1) A key factor of a stable nanocomposite processing technology is the prevention of the degradation of carbon nanotubes and graphene during the sintering process.
- (2) The selection of the ceramic matrix and quality assurance of the reinforcing phase is a fundamental step because the secondary reinforcing phases (carbon nanotube, graphene) and their quality determine the toughness and work of fracture.
- (3) One of the problematic issues in composite preparation is the improvement of the homogeneity of the dispersion of reinforcing phases within the ceramic matrix. Agglomeration of CNTs and graphene cause porosity increase which in turn decrease the strength by initiation of flaws. Increasing milling time and ultrasonic agitation of the powder mixtures can solve this problem.
- (4) Two factors have important role for the resulting composites; the effect of different sintering kinetics on the phase transformation of the silicon nitride matrix and the effect of degradation of the carbon reinforcing phase.
- (5) The more lengthy HIP and HP sintering processes allow completion of the α to β - Si_3N_4 transformation compared to SPS where the α - Si_3N_4 was preserved due to working with enhanced electrical field, rapid heating and very short sintering times.
- (6) The highest hardness of the nanocomposites compared to the monolithic material is mainly dependent on the residual porosity that remains in the material after the sintering and good homogenization of the reinforcing phase.
- (7) Modulus of elasticity of ceramic matrix composites with graphene addition showed higher values compared to composites with carbon nanotubes independent of the sintering method applied.
- (8) Graphene addition has a beneficial role in the re-arrangement of grains during sintering at low nitrogen pressure (2 MPa, in the case of GPS) which at the end of sintering results in more dense structures with higher 3-point bending strengths than for CNT addition.
- (9) The introduction of carbon nanotube or graphene reinforcing phases with higher coefficients of thermal expansion toughen the final Si_3N_4 matrix composite.
- (10) Carbon nanotubes and graphene contribute significantly to the decrease of friction coefficient. Increasing the amount of carbon phase has beneficial role showing lower frictional response of Si_3N_4 ceramic composites.
- (11) The specific conductivity range of the CNT added composites processed by GPS or HIP can reach 10 S m^{-1} which allows processing by electrical-discharge machining (EDM).

Short Fiber Ceramic Matrix Composites (SF-CMCs)

Walter Krenkel, Stefan Flauder, and Georg Puchas, University of Bayreuth, Bayreuth, Germany

Introduction

Reinforcing ceramics with fibers allows them to overcome their brittleness and induce fracture toughness in the material and damage tolerance to the ceramic component. In many cases, the fibers will provide sufficient mechanical properties even if their length is far smaller than the dimension of the component, offering technological advantages in terms of near-net shape producibility and/or economical benefits compared to continuous fibers. Short fibers or chopped fiber bundles are typically produced by cutting long fibers or rovings to lengths from several millimeters to few centimeters. In comparison with polymeric or metallic matrices, the minimum fiber length for the reinforcement of ceramic matrices is typically one order of magnitude higher and is mostly defined rather by empirical knowledge than theoretical concepts. Short fiber ceramic matrix composites have been developed both as non-oxide matrix composites with ceramic or carbon fiber reinforcements as well as oxide matrix composites in which non-oxide or oxide fibers are incorporated in an oxide matrix.

The need to use short fibers in composites with brittle ceramic matrices can be driven by a multiplicity of motivations. Of course, there is the economical aspect of cost reduction by replacing long fibers and 2D-fabrics with short fibers as well as the application of certain near-net shape fabrication methods (Zuber and Heidenreich, 2006). The main objective for short fiber reinforced CMCs is the adjustment of structural and functional properties in the final composite. Compared with the properties of the pristine ceramic matrix material, the fiber addition in the final composite can lead to:

- (1) Improved damage tolerance, often accompanied by an increased strain-to-failure.
- (2) Increased tensile strength for comparable weak or porous matrices (Slosarczyk *et al.*, 2000).
- (3) Increased resistance against creep (Pachalis *et al.*, 1990).
- (4) Adjusted thermal expansion and thermal conductivity e.g., for a low coefficient of thermal expansion (CTE) and high thermal conductivity in the composite (Krödel *et al.*, 2002; Song *et al.*, 2003).
- (5) An appropriate frictional performance (Krenkel *et al.*, 2002).
- (6) Tailored absorption behavior of electromagnetic waves (Cao *et al.*, 2010).

Some prevalent applications of short fiber CMCs benefit from the combination of damage tolerance with the inherent properties of the ceramic constituents, like high melting point, hardness, oxidation resistance, and high resistance against thermal shock, rendering them very suitable for the use in environments with high thermo-mechanical loads.

Before discussing the principles of influencing effects of the short fibers on the desired composite properties, we have to address the state of the short fibers within the composite. The short fibers can occur in the matrix either as distributed single fibers, or more commonly as distributed short fiber bundles, due to their cutting from fiber rovings with a distinctive filament number. In contrast to continuous fiber reinforced CMCs, which are often derived from rovings or from fabrics with a 2D fiber orientation, resulting in a high anisotropy, it is easier to achieve quasi-isotropic properties in one plane with short fiber reinforced CMCs. This is due to the random orientation of short fiber bundles during fabrication methods like compression molding. The primary parameters, which have a decisive impact on the composite properties, and also determine the possible mechanisms of action of the reinforcement in the composites are: the inherent material properties of the constituents (e.g., quantities of stiffness, Poisson's ratio and CTE), the fiber volume content, the length of the short fibers or short fiber bundles, the diameter of the fibers, the aspect ratio of a single fiber defined by the length divided by the diameter, the fiber orientation from random to orientated, and the bonding strength between fibers and matrix as well as their origin (chemical and/or physical bonding).

Mechanisms of Short Fiber Reinforcement

In contrast to the existing comprehensive models and understandings about the mechanical behavior and properties of continuous fiber reinforced CMCs (Evans and Zok, 1994), only a few consistent models exist for short fiber CMCs. Most of the existing insights and model conceptions for short fiber CMCs are based upon empirical approaches and are often limited to a single CMC material class or to specific short fiber orientations and hence are far away from general applicability. It has to be pointed out, that the majority of theories for the estimation and prediction of properties of short fiber CMCs, and their interdependence from structure, were originally derived for composites with polymeric or metallic matrices and fibers. Some model boundary conditions for these can be in accordance with the conditions prevailing in distinctive short fiber CMC materials and could therefore be used as a first estimation of properties and their relation with structure and composition.

Fig. 1 Schematic of the toughening mechanisms stress shielding, crack bridging, pull-out, crack deflection and debonding. From Evans, A.G., 1990. Perspective on the development of high-toughness ceramics. *Journal of the American Ceramic Society* 73, 187–206. Copyright John Wiley & Sons, Inc.

Damage Tolerance and Extrinsic Toughness

The achievement of a damage-tolerant material behavior, in terms of an extrinsic toughening (Launey and Ritchie, 2009), is one of the most pronounced endeavors for short fiber CMCs. Mechanisms of extrinsic toughening, such as stress shielding of crack bridging fibers and fiber pull-out, take effect after a prolonged crack growth and occur in the wake of the crack tip. In contrast to the intrinsic toughness of a material, which determines the initial resistance against crack growth due to mechanisms within or ahead of the crack tip, the extrinsic toughening often leads to a higher resistance against the crack growth with increasing damage and crack extension.

The fiber reinforcement often enables an increase of the total strain-to-failure of the composite above the level of the brittle fiber and matrix. Due to the fiber reinforcement, different energy dissipating mechanisms can occur during failure. Stress shielding by fibers in front of a crack transfers stress from a crack within the matrix to the fiber with a higher modulus of elasticity and strength, thereby reducing the stress intensity of the crack in the matrix. If the fibers induce residual stress fields in their adjacent regions within the matrix, a crack can be deflected or branched, causing it to meander around the fibers. This deflection can also occur directly at the fiber/matrix-interface. If a crack is deflected around a sufficiently strong fiber, the crack can be elongated, while the fiber is still bridging the gap. For this purpose, the fiber needs to be long enough to span the crack. With further elongation the fiber can break somewhere away from the crack opening and the remaining fiber fragment can be pulled-out, thereby dissipating energy by frictional sliding. Fig. 1 sums up principle models of toughening mechanisms.

Except for the stress shielding by fibers and the crack branching, debonding of fiber and matrix is a prerequisite for all toughening mechanisms, such as crack deflection at the fiber matrix interface, crack bridging and pull-out of fibers from the matrix during proceeding crack growth. In order for debonding to occur, a sufficient bonding between fiber and matrix is necessary. If the bonding is too low, this will only cause the fibers to act as flaws in the matrix and no load transfer appears. A sufficiently strong bond between fiber and matrix can be achieved with the choice of processing, constituents, and/or fiber coatings, leading to the adjustment of the suitable interface design or weak matrices in the case of porous or gradient matrices (Zok, 2006; Koch *et al.*, 2008). The capacity of pull-out and friction mechanisms is dependent on the fiber length, resulting in a toughness increase for short fiber reinforced CMCs, which is often less pronounced than for continuous fiber reinforced CMCs. The boundary conditions for fiber pull-out depend on the embedded fiber length, the shear strength, the ratio of the elastic moduli of fiber and matrix, and the stress distribution within the fiber (Lawrence, 1972). This theoretical concept can predict the situation, in which a fiber of minimum length will be pulled-out of the matrix instead of breaking without any pull-out. If a short fiber CMC with unidirectional (UD) fiber alignment has an optimum fiber length, so that all the fibers in a crack will be pulled-out instead of fracturing, the toughening effect by the pull-out mechanism can be greater than for long fiber reinforcement of the same material (Budiansky and Cui, 1995). Of course, the strength of the continuous reinforced material will always be higher.

The quantitative estimation of toughness values for a given short fiber composite is intricate, as the amount of the single toughening effects and their contribution to the total composite toughness is difficult to determine. An approach for the calculation of the toughness values for the pull-out and the fiber bridging mechanisms of short fiber reinforced ceramics is presented by (Becher, 1991) considering the determination of the pull-out length regarding (Budiansky *et al.*, 1986). Despite the fact, that the necessary calculated pull-out length of 26 μm was satisfied with carbon fibers longer than 100 μm in a silicon nitride matrix, and a desired pull-out mechanism could be found, damage tolerance and quasi-ductility was not observed in the final composite (Herzog *et al.*, 2007). Hence, there is no guaranty, that the activation of one or more principal toughening mechanisms will lead to a damage tolerance of the material.

The influence of interface debonding, matrix cracking stress and frictional conditions between fiber and matrix on the overall toughness of composites can be modeled for the special case of unidirectional short fiber reinforcements (Budiansky *et al.*, 1995). A model with a probabilistic approach describes the toughness of short fiber CMCs with aligned or randomly oriented fibers with

Fig. 2 Criteria for fiber cracking or debonding depending on (a) the relation of interface (i) and fiber (f) fracture energy and the elastic mismatch and (b) the inclination of the crack to the fiber. From Evans, A.G., He, M.Y., Hutchinson, J.W., 1989. Interface debonding and fiber cracking in brittle matrix composites. *Journal of the American Ceramic Society* 72, 2300–2303. Copyright John Wiley & Sons, Inc.

regard to the pull-out effect, the fiber shape parameter, the fiber inclination, and the fiber strength distribution (Suemasu *et al.*, 2001). Too much inclination between the fibers and the crack leads to fiber breakage instead of pull-out, thus, the toughness for randomly oriented short fiber composites was found to be lower compared to unidirectionally aligned short fiber reinforced composites.

Debonding of Fiber and Matrix

The behavior of a crack in the interface region between the matrix and the fiber plays an important role in the performance of the composite. The debonding process is a requirement for most toughening mechanisms. If a matrix crack, driven by an external load, is propagating towards the fiber, it could either penetrate or bypass the fiber. To bypass, a debonding between fiber and matrix is necessary. The debonding can occur as a failure in the interface, the coating, or the matrix itself. The principal debonding conditions and their mechanisms are well understood and extensive models are available. A first approach explains the debonding between two elastic and isotropic materials by means of an energy release rate criterion of a deflection or penetration of the crack (He and Hutchinson, 1989). It also includes the influence of different angles between the crack, the interface, and the load direction. Beside this general approach for the coupling of two materials, a model for brittle matrix composites was evolved to describe the conditions for debonding or fiber cracking based on a fracture energy criterion of interface and fiber (Evans *et al.*, 1989). The schemes for debonding conditions are depicted in Fig. 2, and consider the elastic mismatch of fiber and interface as well as the inclining of fiber, crack, and load direction. Hence, it is a very powerful tool for material design and development in order to adjust the right combination of fiber and matrix, fiber coating, or interface design. The model shows, that debonding appears more readily, if a crack perpendicular to the load direction approaches a fiber with an axis not perpendicular to the fiber. The smaller the angle between fiber and crack, the easier the debonding. Furthermore, if the crack approaches the fiber at a smaller angle, the debonding can occur at a higher ratio of interface fracture energy to fiber fracture energy. In addition, a smaller angle between crack and fiber can also affect the failure mode of the fibers, which can lead to kinking instead of rupture. This has consequences for short fiber reinforced CMCs, as the fiber distribution function and the load direction become crucial for the overall material behavior. The debonding condition in the short fiber CMC can become a function of the spatial orientation of the single fibers and fiber bundles within the material and therefore, the enabled toughening mechanisms related to debonding become a function of position and orientation itself.

Advanced debonding models make it possible to account for residual stresses within the composite, which are quite common for CMCs. It is possible to extend the fracture energy criterion with the integration of friction after debonding, which is caused by residual compressive stresses in the composite between fiber and matrix (Hutchinson and Jensen, 1990). If residual tensile stresses between fiber and matrix are present, debonding can lead to a state free of friction after interface debonding (Charalambides and Evans, 1989). The fiber debonding conditions can also be evaluated under combined mechanical and thermal loads, at which the residual stresses arise from a change of temperature (Charalambides, 1990). The last three models should be considered in the assessment of damage tolerance due to fiber pull-out, as the influences of friction and residual stresses play a key role for the amount of energy absorption. Although the general conditions for debonding in CMCs with a weak matrix are addressed partly by the consideration of elastic mismatch in the model of Evans, He, and Hutchinson (Evans *et al.*, 1989), a more

emphasized description was derived for debonding conditions predominant in weak matrix CMCs with strong interfacial bonding (Tu *et al.*, 1996).

Load Transfer Between Matrix and Fiber

The load transfer from a stressed matrix to the fiber is treated with different assumptions leading to so called shear lag models. Models for short fiber reinforced CMCs are only of limited practical use, since the desired mechanism of debonding is not addressed in the existing models and most of the model assumptions are far away from the conditions apparent in short fiber CMCs under load. For example, most of the shear lag models consider an alignment of the external load, shear load from matrix to fiber, fiber orientation and the axial fiber load. This arrangement will be rare in real short fiber CMC materials. Hence, the shear lag models with their simplified approaches provide only basic insights in intricate problems.

The linear elastic shear lag model assumes, that there is only a load transfer from the matrix to the fiber via shear load with a perfect bonding between fiber and matrix, no radial stresses due to clamping forces or elastic mismatch, no load transfer at the fiber ends, and the modulus of the fiber is greater than that of the matrix (Cox, 1952). This model can be used to calculate the axial stress distribution within the fiber and the interfacial shear stress between matrix and fiber. The axial fiber stress will increase from both fiber ends with a hyperbolic function and reach a maximum in the middle of the fiber. The shear stresses within the matrix start from zero in the middle of the fiber and increase inhomogeneously and steeply towards the fiber ends. With the additional assumption of a constant shear load over the whole fiber length, the elastic-plastic model can derive a critical aspect ratio for the maximum exploitation of the fiber strength (Kelly and Tyson, 1965). The constant shear load was initially an interpretation of a given yield strength for metal matrix composites. For the case of CMCs it was assumed that the constant shear load for this model could be the constant friction state between fiber and matrix. A constant shear load assumption leads to a linear increase of axial fiber stress from the fiber ends towards the fiber middle. This axial stress can attain the maximum fiber strength level ($\sigma_{\text{fiber,max}}$), if the fiber aspect ratio ($\frac{l}{d}$) is high enough to transfer an external load via the known and constant shear strength (τ_i). Hence, it would be possible to derive a critical aspect ratio or a critical fiber length (l), which would take full use of the maximum fiber strength, if the diameter (d) of the fiber is set for a known fiber and interface shear strength (Eq. 1). If the aspect ratio is smaller, the maximum axial stress in the fiber will be below fiber strength.

$$\left(\frac{l}{d}\right)_{\text{crit}} = \frac{\sigma_{\text{fiber,max}}}{2 \cdot \tau_i} \quad (1)$$

This model can be used to estimate pull-out or breakage of fibers and is often the prerequisite to derive models for the estimation of stiffness, strength and toughness in composites.

The application of the shear lag model to short fiber reinforced polymer composites leads to the experimental validation of strength dependency from fiber length and critical fiber lengths in the range of a few hundred μm (Fu and Lauke, 1996). However, the practical applicability for CMC materials seems questionable. A calculation for a CMC with an oxide fiber reinforcement of Nextel™610 with a fiber strength of 3300 MPa and a diameter of 12 μm (Wilson and Visser, 2001) within an oxide matrix and an interface shear strength of 2–12 MPa (Weaver *et al.*, 2006) leads to critical fiber lengths of 1.7–10 mm. The experimental determination of the critical fiber length in short carbon fiber reinforced carbon using a double lap joint method leads to a value of 52 mm (Heim *et al.*, 2013). These values are up to two orders of magnitude greater than those for polymer matrix composites. An obvious change of bending strength was not observed for short carbon fiber reinforced SiC composites, if the fiber lengths were varied from 10 to 40 mm (Zuber and Heidenreich, 2006) or 6–24 mm (Liensdorf *et al.*, 2019).

Further developments of shear lag models try to refine the explanatory power with the coverage of more and more practical constraints. The load transfer from matrix to the fiber across the fiber ends can be considered for aligned short fiber composites, leading to a refinement of stress fields in fiber and interface (Fukuda and Chou, 1981). The inclusion of residual stresses and matrix cracking for unidirectional continuous fiber reinforced CMCs under tensile load, allows a better approximation of stress distribution as well as the estimation of debonding lengths (Lee and Daniels, 1992; Daniels *et al.*, 1993). Some attempts also account for residual axial stresses caused by thermal mismatch for short fiber reinforced CMCs (Hsueh and Becher, 1996). A refinement of axial stresses of the fiber in dependency of the aspect ratio could be achieved, but radial stresses were also not considered in this modified shear lag model. A critical assessment for the use of shear lag models for unidirectional composites states that it is a sufficient analytical tool to estimate axial stresses for axisymmetric stress states (Nairn, 1997). However, the predictions of shear stresses and energy release rates are of low accuracy and the associated errors are strongly dependent on the ratio of the fiber and matrix Young's moduli. The shear lag approach is also not applicable to low fiber volume contents (Nairn, 1997).

Estimate Composite Strength

Compared to obtaining an increased damage tolerance and toughness by incorporating short fibers into a matrix, the goal to increase the strength is only a secondary intention. To achieve a strength increase with short fiber reinforcement, the strength of the fibers has to be much higher than the strength of the matrix and strong fiber matrix bonding is needed. Following this approach leads to a brittle composite. With this assumption, the load transfer could be estimated with existing shear lag models, meaning an

Fig. 3 Mono-modal (fiber length 24 mm) and bi-modal (fiber lengths 6 and 24 mm) fiber distributions in a short fiber CFRP composite prior to pyrolysis. Reproduced from Liensdorf, T., Langhof, N., Krenkel, W., 2019. Mechanical properties of PEEK-derived C/SiC composites with different fiber lengths. *Advanced Engineering Materials* 21 (5), 1800835. Copyright Wiley-VCH GmbH.

increasing fiber length leads to improved utilization of the fiber strength and therefore, a higher composite strength. The models for the estimation of the strength of unidirectional aligned short fiber composites show a dependency from fiber volume fraction, fiber aspect ratio and the ratio of the modulus of elasticity (Chen, 1971). Existing models for brittle polymeric matrix composites can predict the stress strain curve and matrix cracking for short aligned fibers according to the maximum strain hypothesis (Chen and Tucker, 1984). The strength estimation for randomly oriented fibers can be made via quasi-isotropic laminate theory following the maximum stress criterion (Hahn, 1975) or maximum strain criterion (Halpin and Kardos, 1978). The mentioned models, however, were not derived for CMC materials and did not consider the debonding aspects for the majority of CMCs with an intended damage-tolerant behavior. Nevertheless, it was shown that the calculated strength values for a damage-tolerant short carbon fiber reinforced $\text{ZrB}_2\text{-SiC}$ composite agreed well with the measured values (Yang *et al.*, 2010). For this purpose, the maximum strain criterion was applied and the decrease of strength from 502 to 445 MPa due to the addition of 20 vol% of randomly oriented carbon fibers was forecast with a strength value of 452 MPa. For 20 vol% short carbon fiber reinforced TiC, it was also possible to calculate the composite strength with a simplified rule of mixtures approach considering the fiber orientation and the fiber strength degradation during the fabrication (Song *et al.*, 2002). In this connection, the predicted flexural strength of 627 MPa was in good accordance with the measured value of 593 MPa.

Estimate Stiffness Quantities

A first approximation for the stiffness behavior can be deduced from general composite models. The stiffness values increase with increasing fiber volume content following certain rules of mixtures within upper and lower bonds. For aligned short fibers, the modulus of elasticity in the fiber direction is strongly influenced by the aspect ratio of the fibers, whereas the Poisson's ratio, the modulus of elasticity perpendicular to the fiber orientation, and the shear modulus are not sensitive to the aspect ratio (Halpin, 1969). For in-plane randomly oriented fibers the laminated plate theory for quasi-isotropic laminates can be applied. The stiffness increases with increasing aspect ratio of the fiber until a threshold, which strongly depends on the relation of the Young's moduli of fiber and matrix, is reached (Halpin and Pagano, 1969).

The lack of reliable analytical models designed specifically for short fiber CMCs leads to the development of better approximations for each individual material via simulation and finite element methods. The elastic properties for C/C-SiC for example, can be numerically modeled with a mesoscale approach considering the size, shape, and orientation of fiber bundles, leading to an agreement of calculated Young's and shear moduli with measured values of a bending test (Airolidi *et al.*, 2013).

Fig. 4 SEM micrographs of the surface (left) and the cross section (right) of a SF-CMC material (C/C-SiC).

Non-Oxide CMCs

Non-oxide ceramic matrix composites comprise mainly the materials carbon and silicon carbide and are abbreviated as C/C, C/SiC, C/C-SiC or SiC/SiC, depending whether the reinforcing fiber is carbon or SiC. In some special cases, for example for hypersonic applications, ultra-high temperature ceramics (UHTCs) like ZrB_2 or HfB_2 are used as main constituent of the matrix materials (Guo *et al.*, 2013; Sha *et al.*, 2015, 2016). Principally, various processing routes exist to infiltrate the fiber preform with the matrix or with a matrix precursor. Conventional powder-based techniques which are used for fabricating monolithic ceramics are mostly not suitable and rather unconventional techniques are applied to avoid damage to the fibers. They can be distinguished between the impregnation either by a gas phase (chemical vapor infiltration, CVI) or by a liquid phase infiltration (Liquid Silicon Infiltration, LSI or Polymer Infiltration and Pyrolysis, PIP). The CVI process needs a stable and stiff fiber architecture such as a fiber preform, and therefore only the LSI and the PIP process are commonly used for the manufacture of short fiber reinforced composites. SiC fibers are up to two orders of magnitude more expensive than carbon fibers and their use as short fibers is therefore limited to special applications (Sciti *et al.*, 2011). As a result, talking about short fiber reinforced non-oxide CMCs usually means referring to C/SiC or C/C-SiC composites.

Most publications and applications of SF-CMCs refer to the LSI process. This technique is based on the impregnation of porous carbon/carbon composites by molten silicon and the reaction of the metallic melt with the carbon to form the silicon carbide matrix. Therefore, this process belongs to the reactive melt infiltration processes (RMI). The fiber preform with its interconnecting network of cracks and pores is infiltrated under vacuum applying only capillary forces and at temperatures at least beyond the melting point of silicon (1415°C). The high reactivity and the exothermal reaction between carbon and silicon require a sophisticated fiber coating or the preservation of dense fiber bundles prior to the infiltration.

The initial step of the process is the fabrication of a carbon fiber reinforced plastic (CFRP) composite with polymeric matrices of high carbon yield. Normally, commercially available resins, such as thermosets (e.g., phenolics) or thermoplastics (e.g., Polyetheretherketone, PEEK) are used to fabricate laminates by compression molding (Krenkel *et al.*, 2002) or other common CFRP techniques like transfer molding (Ahmad *et al.*, 2020) or injection molding (Müller-Köhn *et al.*, 2020). The latter two technologies suffer from the drawback that the chopped fibers are further shortened considerably by the shear forces in the extruder during the compounding and injection step and that the fiber bundles cannot be preserved, resulting in single fibers with a length of only some few hundred μm . In contrast, the compression molding process allows the chopped fibers to maintain their original length (mm to cm), as well as maintaining the integrity of the bundles over the total CFRP forming process.

In order to reach a high fiber volume content as well as a homogenous fiber distribution, different fiber lengths can be combined to form the reinforcement. Fig. 3 depicts schematic diagrams and the corresponding microstructures of CFRP composites with a mono-modal fiber distribution of fibers with a length of 24 mm, and a bi-modal fiber distribution of fibers with 6 and 24 mm in length, respectively. The bi-modal fiber preform results in a more quasi-isotropic in-plane fiber orientation with a higher fiber volume content of 35% in comparison with the mono-modal fiber preform.

After curing or solidifying the matrix, the composites are pyrolysed under inert conditions (e.g., nitrogen or vacuum) at temperatures beyond 900°C to convert the polymeric matrix to amorphous carbon. The pyrolysis of the CFRP composite leads to a volumetric contraction of about 50% of the neat polymer. As this contraction of the polymer is hindered by the embedded fibers, the macroscopic shrinkage of the composite during pyrolysis is considerably lower. The shrinkage impediment is dependent on the fiber alignment and on the fiber/matrix bonding in the interphase. In the direction of the fiber orientation the macroscopic shrinkage is close to zero with the result that the matrix contraction leads to a microscopical network of cracks within the resulting C/C composite. The fiber/matrix bonding strength plays an important role for the crack formation. It can be modified by a fiber coating (e.g., pyC) or by a thermal pretreatment of the carbon fibers in order to adapt the functional groups on the carbon fiber surfaces. The latter method is often used due to its easy and cheap approach in contrast to the fiber coating process and is described well in the literature (Sha *et al.*, 2017; Liensdorf *et al.*, 2019). In general, the higher the fiber/matrix bondings the higher the tendency to preserve and form dense fiber bundles, comprising hundreds of filaments, interconnected with a translaminar crack

Fig. 5 Transverse thermal conductivity of C/C-SiC composites with 40 mm chopped fibers versus fiber volume content in the CFRP stage. Reproduced from Krenkel, W., Heidenreich, B., Renz, R., 2002. C/C-SiC composites for advanced friction systems. *Advanced Engineering Materials* 4, 427–436. Copyright Wiley-VCH GmbH.

system. These microcracks represent the open porosity of the C/C composite which is subsequently infiltrated with molten silicon to form the silicon carbide matrix (Krenkel, 2004, 2005, 2008; Krenkel *et al.*, 2002; Krenkel and Berndt, 2005).

After the siliconizing step, the resulting C/C-SiC composite comprises short carbon fiber bundles, embedded in a multi-phase matrix of carbon, silicon carbide and residual silicon. The density is between 2 and 2.5 g cm⁻³ with an open porosity of up to 5%. **Fig. 4** shows a typical cross-section and a top view of a short fiber CMC with fiber lengths between 6 and 40 mm.

The fiber/matrix interphase and the resulting bonding forces are affected by the type of carbon fiber. Guo *et al.* compared pitch and PAN derived fibers with lengths of 6 mm and reported that the flexural strength of pitch-based C/C-SiC composites was higher at room as well as at high temperature (800°C). Also, the thermal conductivity was higher compared to PAN fiber C/C-SiC and increased with the fiber volume content of the composite (Guo *et al.*, 2012). For PAN fibers with low thermal conductivity, the relationship between transverse thermal conductivity is vice versa: The higher the fiber volume content, the lower the thermal conductivity as lower fiber contents result in a higher amount of SiC in the matrix which shows a higher thermal conductivity than the fibers (Krenkel *et al.*, 2002). **Fig. 5** shows this correlation for C/C-SiC composites with 40 mm chopped fibers, referred to the fiber volume content in the intermediate CFRP stage.

Besides the fiber volume content, the length and the orientation of the fibers to the loading direction are the most important influences on the mechanical and thermophysical properties of SF-CMCs. In an experimental study with 6 mm carbon fibers, Hausherr *et al.* reported an increase of 50% in flexural strength and of 80% in stiffness, if the loading occurs in direction of the fiber alignment, compared with randomly oriented fibers (Hausherr *et al.*, 2015). **Table 1** summarizes the relationship between the fiber alignment and the loading direction and shows, that the mean value of different unidirectional reinforced SF-CMCs with angles between 0° and 90° to the load direction is very similar to the flexural strength of a randomly oriented, isotropic reinforced SF-CMC with the same fibers.

In contrast to continuous fiber reinforced CMCs no international standard exists for testing SF-CMCs in terms of dependence on the fiber orientation and fiber length. Studies of Shi *et al.* with C/C-SiC composites showed, that the flexural testing of SF-CMC should be conducted with a four point bending set-up rather than with a three point configuration (Shi *et al.*, 2015). It is recommended, that the width of flexural test coupons should be triple the fiber length and the span-to-thickness ratio should be 10. For longer fibers (10 mm and more) the width should be twice the fiber length and the span-to-thickness ratio should be at least six (Shi *et al.*, 2017).

Fig. 6 depicts the influence of fiber volume content, fiber length and fiber orientation on the mechanical properties of a C/C-SiC composite. Whereas higher fiber contents increase the flexural strength slightly, longer fibers (24 mm instead of 6 mm length) show a more pronounced increase of the strength level. In the case where all fibers are aligned in one direction (unidirectional reinforcement), this short fiber UD-composite shows much better properties compared to randomly oriented composites with a quasi-isotropic behavior.

Compared with continuous fiber reinforced composites the mechanical properties of short fiber reinforced composites are somewhat lower. **Fig. 7** shows the flexural strength, the strain-to-failure and the Young's modulus of a mono-modal reinforcement of C/C-SiC with fibers of 6, 12 and 24 mm in length. As for all short fiber reinforcements, the scatter in the property data is higher in comparison to 2D reinforcements, for example fabrics. The values in general are in the range of 100 MPa for the flexural strength, 30 GPa for the Young's modulus and 0.5% strain-to-failure. These properties are also achieved with a bi-modal short fiber reinforcement (**Fig. 8**) with the combination of 6 and 12 mm fibers, 6 and 24 mm as well as 12 and 24 mm fibers, combined with a more homogenous microstructure (Liensdorf *et al.*, 2019).

As for all CMCs, the conventional determination of the Mode I fracture toughness does not correctly describe the quasi-ductile behavior of the composites. Typically, the fracture toughness K_{IC} is on the same level as that of SiC or other monolithic engineering

Table 1 Influence of fiber orientation on the mechanical RT-properties of SF-C/C-SiC (fiber length 6mm) (Hausherr, Eitel, Krenkel, 2015)

Short Fibers (6mm)	Fiber Orientation α								Isotropic
	0°	15°	30°	45°	60°	75°	90°	Mean Value	
Flexural Strength [MPa]	67	62	48	43	30	28	25	44	45,6
Young's Modulus [GPa]	45	40	30	25	22	19	16	28	25
Strain [%]	0,17	0,16	0,17	n.a.	0,17	0,16	0,16	0,16	0,17

**Fig. 6** Dependence of fiber length, fiber content and fiber orientation on the mechanical properties of SF-C/C-SiC composites.

ceramics. Inoue *et al.* measured K_{IC} values of about $4 \text{ MPa}\sqrt{\text{m}}$ and Sha *et al.* of up to $7.6 \text{ MPa}\sqrt{\text{m}}$ (Inoue *et al.*, 2013; Sha *et al.*, 2017). However, the damage-tolerant behavior of these composites is much better than these properties imply. Fig. 9 shows the typical fracture surface of a C/C-SiC composite reinforced with 24 mm long fibers, which had been thermally pretreated at 700°C to reduce the fiber/matrix bonding at the interface.

The current most important applications of short fiber reinforced CMCs are brake disks for high-performance cars (Krenkel and Thébault, 2014). More than 200,000 C/C-SiC brake disks are produced annually in increasing numbers, corresponding to a production volume of approximately 1000 tons of SF-CMC every year. Compounds of chopped fiber rovings and powdery phenolic resins are mixed, filled in a mold with a geometry similar to the desired shape of the disk and subsequently compression molded, pyrolysed and siliconized. Applying a bi-modal fiber distribution, very complex and thin-walled designs of internally ventilated rotors are manufactured in a near-net shape process (Fig. 10). In comparison with metallic rotors the low density of this type of SF-CMC (below 2.5 g cm^{-3}) results in weight savings of up to 50% of the braking system of a passenger car.

Oxide CMCs

The reinforcing short fibers for oxide matrices can be either oxide or non-oxide. The following description of the current status of oxide matrix composites will concentrate on polycrystalline fibers and will forego all whisker-reinforced materials, although whiskers can reach similar dimensions as some of the short fibers described.

Non-Oxide Fiber Reinforcements

An overview of oxide matrices reinforced with non-oxide short fibers is shown in [Table 2](#). The most commonly used non-oxide fibers for the reinforcement of oxide matrices are carbon fibers with diameters in the range of 5 μm to 13 μm . All described non oxide fiber/oxide matrix composites, with the exception of the ones produced by ([Langhans and Roeder, 1992](#)), include at least one pressing step during fabrication, which indicates the desire to obtain a dense matrix. Since all of the manufacturing techniques for non-oxide fiber/oxide matrix composites in the literature contain at least either a pressing step or an extrusion step and some even contain an additional milling step, the initial fiber length is shortened and the actual fiber length in the composite is considerably smaller. This final length is more likely to be in a similar range as the 20–150 μm described by ([Dorner-Reisel et al., 2004](#)) and the length distributions with fiber lengths less than 280 μm and 180 μm reported by ([Ye et al., 2008](#)).

The reinforcement of biocompatible as well as bioactive matrices such as calcium phosphate ([Park and Vasilos, 1997](#)) and hydroxyapatite ([Slosarczyk et al., 2000](#); [Dorner-Reisel et al., 2004](#)) with short carbon fibers was motivated by improving the mechanical properties of the matrix materials for possible applications as implants. The enhancement of mechanical properties was also the objective for the reinforcement of alumina ([Jia et al., 2018](#)), BAS ([Ye et al., 2008](#); [Ma et al., 2009](#)), β -SiAlON ([Demir, 2012](#)) as well as alkali-lime-silica glass ([Langhans and Roeder, 1992](#)) with carbon and/or silicon carbide short fibers. In contrast to this, alumina was reinforced by small amounts of carbon fibers (0.1 wt%–0.5 wt%) in order to influence its mechanical as well as its dielectric properties ([Huang et al., 2012, 2013, 2014](#)). The reinforcement of silica with 20 wt% carbon fibers by [Cao et al.](#) was pursued exclusively with regard to the improvement of the dielectric properties ([Cao et al., 2010](#)).

Due to the relatively dense matrices, the mechanical properties such as flexural strength and fracture toughness of reinforced matrices improved for most of the materials compared with unreinforced matrices, despite the short fiber length. One notable exception is the work of [Huang et al. \(2012\)](#), where the strength and hardness was decreased slightly by the introduction of carbon fibers into the matrix. This was attributed to big grains and a non-uniform grain size distribution as well as to less strong interfacial fiber/matrix bonds ([Huang et al., 2013](#)).

Extensive studies on the reinforcement of Pyrex glass, and also of soda-lime glass, lithia alumino-silicate glass-ceramic, alumina and magnesia with carbon fibers were carried out by ([Sambell et al., 1972](#)), while others concentrated just on the reinforcement of Pyrex glass with carbon fibers ([Phillips, 1972](#); [Phillips et al., 1972](#)).

Oxide Fiber Reinforcement

A summary of all-oxide short fiber reinforced CMCs is presented in [Table 3](#). Generally, one can distinguish three types of short oxide fiber/oxide matrix composites, based on the type of reinforcing fiber. These are.

- (1) Glass or silica (quartz) fibers ([Mishra et al., 2008](#); [Mishra et al., 2009](#); [Yunus et al., 2017](#)).
- (2) Low performance thermal insulation fibers, which include amongst others Saffil®, Denka®, Fiberfrax® and Zircar®; fibers ([Boussois et al., 2014](#); [Hua et al., 2013](#); [Liu et al., 1998](#); [Naskar et al., 2004](#); [Naskar et al., 2009](#); [Özkal and Uçar, 2010](#); [Papargyri et al., 2003](#); [Russell-Floyd et al., 1993](#); [Sambell et al., 1972](#); [Sheldon and Lewis, 1976](#); [Wang et al., 1991](#); [Yunus et al., 2017](#)).

Table 2 Literature survey summary of non-oxide short fiber reinforced oxide matrices

Matrix	Fiber	Fiber content	Initial fiber length	Fiber diameter	Reference
Al ₂ O ₃	C	0.22–0.44 wt%	1–3 mm	7.8 μm	Huang <i>et al.</i> (2012)
Al ₂ O ₃	C	0.1–0.3 wt%	2–4 mm	5–7 μm	Huang <i>et al.</i> (2013)
Al ₂ O ₃	C	0.1–0.5 wt%	2 mm	5–7 μm	Huang <i>et al.</i> (2014)
Al ₂ O ₃	C	5–15 vol%	2 mm	7 μm	Jia <i>et al.</i> (2018)
Ca ₃ (PO ₄) ₂	C	5 vol%			Park and Vasilos (1997)
Hydroxyapatite	C	20 vol%		8–9 μm 12–13 μm	Slosarczyk <i>et al.</i> (2000)
Hydroxyapatite	C	20 vol%	20–150 μm (milled)	5 μm	Dorner-Reisel <i>et al.</i> (2004)
SiO ₂ , Feldspar, Kaolin clay	C	0.25–1 wt%	1 mm	7 μm	Yunus <i>et al.</i> (2017)
SiO ₂	C	20 wt%	1 mm	7 μm	Cao <i>et al.</i> (2010)
Glasses, Glass-ceramics, Al ₂ O ₃ , MgO	C	5–40 vol%		8 μm	Sambell <i>et al.</i> (1972)
BAS	C	20–40 vol%	3–5 mm	6–8 μm	Ye <i>et al.</i> (2008)
Pyrex-Glass	C	19.8–57.1 vol%		8 μm	Phillips (1972)
Pyrex-Glass	C	22.9–59.5 vol%		8 μm	Phillips <i>et al.</i> (1972)
BAS + Si ₃ N ₄	C	20 vol%	2–4 mm	7 μm	Ma <i>et al.</i> (2009)
	SiC	20 vol%	2–4 mm	12 μm	
β-SiAlON	SiC	5–15 vol%	1–2 mm	14 μm	Demir (2012)
Alkali-lime-silica glass	SiC	5–30 vol%	1 mm	15 μm	Langhans and Roeder (1992)

- (3) High performance fibers, for example the DuPont™ FP, ALMAX™ and Nextel™ fibers, although only the Nextel™ fibers are commercially available today (Böttcher *et al.*, 2019; De With and Corbijn, 1989; Knepper *et al.*, 1997, 1998; Tülümen *et al.*, 2017).

It is noteworthy, that, in contrast to the non-oxide reinforcements, the fiber diameters used for oxide fiber/oxide matrix composites vary to a larger degree, namely from 3 μm to 20 μm. With diameters less than 5 μm, some of the low cost thermal insulation fibers might even be harmful to the human respiratory tract/system. Their matching CTE as well as their low thermal conductivity were the reasons, why glass (Mishra *et al.*, 2008) and silica (Mishra *et al.*, 2009) short fibers were investigated for the reinforcement of ceramic silica foams as thermal protection systems for space applications. The challenge of dispersing these 20–25 mm short fibers at a relatively high content of 10 wt% was addressed in both of these publications.

A comparative study on the properties of continuous as well as short fiber reinforced composites, prepared by a freeze gelation route, reported the influence of porosity on the mechanical properties of short oxide fiber/oxide matrix composites (Russell-Floyd *et al.*, 1993).

Yunus *et al.* used a SLA 3DP process to produce silica/Feldspar/Kaolin + Ball clay matrix composites reinforced with either carbon, silica or alumina fibers (Yunus *et al.*, 2017). They investigated the mechanical properties on unreinforced and reinforced matrices, as well as the influence of fiber orientation. The alignment of the fibers as well as the increase of the fiber content led to an increase of the mechanical properties.

For the same reason as (Slosarczyk *et al.*, 2000; Dorner-Reisel *et al.*, 2004) used short carbon fibers for the reinforcement of hydroxyapatite, short alumina fibers of the type ALMAX™ (Knepper *et al.*, 1997, 1998) and DuPont™ FP (De With and Corbijn, 1989) were used, having the additional advantage of being bio-compatible.

The only reports of using a short fiber preform instead of short fibers and subsequent forming steps are by Naskar *et al.* (2004) and Naskar *et al.* (2009). They used a vacuum-infiltration process to infiltrate fiber preforms with different matrix-forming sols (zirconia-yttria, alumina-zirconia, alumina, alumina-silica) and investigated the influence of different numbers of infiltration cycles as well as of varying sintering temperatures. The highest flexural strength obtained in these studies was 31.1 MPa, by a zirconia-yttria-sol infiltrated alumina short fiber preform with four infiltration cycles and sintered at 1400°C (Naskar *et al.*, 2009). No account of the porosity of the samples and its influence on the mechanical behavior was given.

As for the non-oxide fiber/oxide matrix composites, most of the literature in Table 2 on glass, silica and thermal insulation fiber reinforced oxide matrix composites describes the decrease of mechanical performance with increasing porosity and therefore aspires to reach dense ceramics. Notable exceptions are given in the work of Sheldon and Lewis (1976), Mishra *et al.* (2008) and Mishra *et al.* (2009). But whereas the desired high porosity in the work of Mishra *et al.* (2008) and Mishra *et al.* (2009) was mostly due to the ceramic foam structure while the struts and cell walls, which contain the fibers, were desired to be dense, the work of Sheldon and Lewis (1976) investigated the fiber reinforcement of porous mullite ceramics for implant applications with the preservation of the porous structure in mind.

All of the literature mentioned above strives for a dense matrix, except Sheldon and Lewis (1976). However, the most common concept for all-oxide CMCs nowadays is the weak matrix concept (WMC), which describes a quasi-ductile fracture behavior

Table 3 Literature survey summary of oxide short fiber reinforced oxide matrices

Matrix	Fiber	Fiber content	Initial fiber length	Fiber diameter	Reference
Fused SiO ₂	E-Glass	1–10 wt%	20–25 mm	10 μm	Mishra <i>et al.</i> (2008)
Fused SiO ₂	E-Glass, SiO ₂ (quartz)	10 wt%	ca. 20 mm	10 μm	Mishra <i>et al.</i> (2009)
SiO ₂	Al ₂ O ₃ -SiO ₂	5–30 vol%			Russell-Floyd <i>et al.</i> (1993)
Mullite	Al ₂ O ₃ -SiO ₂	≤ 33 vol%			Sheldon and Lewis (1976)

Al ₂ O ₃	Al ₂ O ₃ (Nextel™610)	0–50 vol%	3.2 mm 50–500 μm in feedstock	11–13 μm	Tülümen <i>et al.</i> (2019)
Al ₂ O ₃ -ZrO ₂	Al ₂ O ₃ (Nextel™610)	20–40 vol%	14 mm (in the CMC)	11–13 μm	Winkelbauer <i>et al.</i> (2021)

derived from a porous matrix in combination with reinforcing fibers (Levi *et al.*, 1999; Zok, 2006). The only commercially available high performance oxide fibers today are the Nextel™ fibers 610 (α-alumina) and 720 (α-alumina-mullite). In the following, the different fabrication techniques for short fiber reinforced oxide matrix composites, based on Nextel™ fibers and designed according to the weak matrix concept, are described exemplarily.

Ceramic Injection Molding

Ceramic injection molding (CIM) is a common process for the production of complex ceramic components. By the introduction of Nextel™610 α-alumina fibers in the feedstock, it is possible to manufacture short fiber reinforced oxide matrix composites (Tülümen *et al.*, 2017; Piotter *et al.*, 2019; Tülümen *et al.*, 2019; Böttcher *et al.*, 2019). During the CIM process, the fibers are broken and oriented, so that the composite contains single short fibers of highly varying length with a preferred orientation in an oxide matrix. Both works do not depict the fracture behavior of the resulting composites in detail, but Böttcher *et al.* (2019) mention that the desired damage-tolerant fracture behavior was not obtained. This is most likely attributed to the separation of the fiber bundles into single fibers, as well as to the short length of the fibers.

For highly porous and therefore weak matrices, a critical fiber length in the range of millimeters as well as a minimum fiber volume content is necessary in order to assure a contribution of the fibers towards the matrix strength and to obtain a damage-tolerant fracture behavior. By the usage of fiber bundles with a length of several mm, instead of single fibers, both issues can be solved.

Impregnation of Short Fiber Preforms

A process for the fabrication of an oxide short fiber bundle preform, which comprises the arrangement of dry fiber bundles, followed by an infiltration with a binder and its stabilization by curing in a compacted state, was developed by Wamser *et al.* (2013). After a subsequent infiltration step of the fiber bundle preform with a ceramic slurry and an additional sintering step above 1200°C, an oxide short fiber reinforced oxide ceramic matrix composite was obtained. A thus prepared

Fig. 11 Schematic depiction of the fiber spraying process.

alumina composite reinforced with 6 mm Nextel™610 short fiber bundles exhibited a flexural strength of up to 90 MPa with a damage-tolerant fracture behavior.

Fiber Spraying Process

Based on common fiber spraying processes for glass fiber reinforced plastic (GFRP) and carbon fiber reinforced plastic (CFRP), a short fiber spraying process for the manufacturing of oxide short fiber bundle/oxide matrix composites has been developed (Knohl *et al.*, 2017b). A schematic depiction of the fiber spraying process is shown in Fig. 11. In contrast to GFRP and CFRP, the preservation of the fiber bundles during the spraying process is of paramount importance. In order to achieve this, the fiber bundles are infiltrated in flight with a low viscosity slurry and are subsequently deposited on the mold surface.

Due to the usage of an alcoholic compound with hygroscopic properties, e.g., glycerol, the water content of the slurry can be adjusted in a similar way to that used by Krenkel *et al.* (2014), Wamser *et al.* (2016), Knohl *et al.* (2017a) and Puchas *et al.* (2020), which yields a pre-impregnated fiber preform (prepreg) with a defined tack ready for lamination. As fiber reinforcements, 14 mm long Nextel™610 10,000 denier (den) fiber bundles with 2550 single filaments were used, while the matrix consisted of alumina and zirconia. By using the fiber spraying process, Nextel™610/Al₂O₃-ZrO₂ composites with a fiber volume content of about 21%, an apparent porosity of 40 vol% and a flexural strength of up to 120 MPa were fabricated. The mechanical properties in xy-plane are not entirely isotropic, because there is a slightly preferred fiber bundle orientation. A typical stress-strain-curve of a three point bending test for these short fiber bundle reinforced composites is shown in Fig. 12(a) and a representative microstructure of the cross-section is presented in Fig. 12(b).

In comparison, a 2D fabric-reinforced Nextel™610/Al₂O₃-ZrO₂ composite with a fiber volume content of 28% had an average flexural strength in 0° of 237 MPa, whereas in 45° to the fiber orientation it exhibited only an average flexural strength of 70 MPa (Puchas and Krenkel, 2018). Therefore, it can be concluded, that the nearly isotropic flexural strength of short fiber bundle reinforced composites is higher than the off-axis flexural strength of 2D fabric reinforced composites, based on identical matrices and fiber type. A feasibility study proved the aptitude of the fiber spraying process for primary forming as well as for shaping, i.e. one can either fabricate flat prepregs to form a more complex component by lamination, or one can fabricate more complex components in a single step by directly spraying on to a complex mold or in a cavity.

Current research focuses on the automation of the fiber spraying process (Fig. 13) and to gain a deeper understanding of the mechanical behavior of short fiber bundle reinforced composites (Schmidt *et al.*, 2020). For this purpose, the mechanical properties of an unidirectional continuous fiber reinforced composite were compared with 14 mm short fiber reinforced composites, which were fabricated by manual lay-up, as well as with one sprayed composite with 14 mm fiber bundles. The short fiber reinforcements were UD, quasi-isotropic (0°/90°/ + 45°/ - 45°)_s, ±45°, randomly oriented and sprayed. The properties of the obtained composites are shown in Table 4.

The average flexural strength of the continuous fiber reinforced UD sample was more than three times higher than that of the 14 mm short fiber bundle reinforced UD sample, with 580 MPa to 163 MPa, respectively. Not surprisingly, the lowest strength was obtained by the “± 45°” composite with an average of 47 MPa, since none of the fiber bundles are oriented parallel to the loading direction.

The fiber orientations of the composites “randomly oriented”, “quasi-isotropic” and “sprayed” were more or less isotropic. The “sprayed” composite showed the highest average flexural strength with 90 MPa, albeit having only about half the fiber volume content of the sample “quasi-isotropic” with an average of 78 MPa. The lower strength of the sample “randomly oriented”, namely 62 MPa, can be attributed to the random lay-up of the short fiber bundles, which amounted in the formation of macropores in the

Fig. 12 Typical stress-strain-curve for short fiber bundle-reinforced composites (a) and typical microstructure of all-oxide composites (b).

Fig. 13 Device for an automated fiber spraying process.

Table 4 Properties of one continuous fiber and several 14 mm short fiber reinforced oxide composites

	<i>Flexural strength [MPa]</i>	<i>Strain [%]</i>	<i>Young's modulus [GPa]</i>	<i>Fiber volume content [%]</i>	<i>Porosity [%]</i>
Continuous fiber (0°)	580 ± 63	0.48 ± 0.05	125 ± 5	39.7	30
14 mm (0°)	163 ± 17	0.18 ± 0.02	105 ± 6	40.3	32
14 mm sprayed	90 ± 19	0.46 ± 0.13	25 ± 2	21.3	40
14 mm (quasiisotropic)	78 ± 12	0.15 ± 0.02	63 ± 8	39.5	32
14 mm randomly oriented	62 ± 12	0.20 ± 0.03	38 ± 6	36.5	37
14 mm (± 45°)	47 ± 5	0.23 ± 0.04	28 ± 2	40.7	30

composite. These are detrimental to the mechanical properties and their formation is verifiable by comparing the fiber volume content and the porosity of the samples “quasi-isotropic” and “randomly oriented”. While the fiber volume content of the sample “randomly oriented” is only 3% lower, the porosity is 5% higher. This is only achievable if macropores are formed. Representative stress-strain-curves of all manually prepared samples are presented in [Fig. 14](#).

Fig. 14 Representative stress-strain-curves (from three point bending tests) of 14 mm short fiber bundle reinforced oxide composites.

In addition to the advantage of being able to produce complex CMC structures by fiber spraying in a single step, the use of short fiber bundles drastically reduces the material costs. At a constant fiber volume content, the costs can be reduced by 26%, comparing 3000 denier fabrics with 3000 denier short fiber bundles and up to 60%, comparing 3000 denier fabrics with 10,000 denier short fiber bundles (Lincoln *et al.*, 2017).

Summary

Short and chopped fibers have been successfully incorporated as discontinuous reinforcing phases in oxide as well as non-oxide matrices. Mostly, the addition of short fibers is used for the ease of manufacturing near-net shaped components without any scrap compared to continuous fibers. Up to now, economical and technological requirements dominate the choice of fiber length and fiber type. In order to act as a reinforcing phase, a minimum fiber length of several millimeters is necessary as well as fiber coatings or well preserved fiber bundles. Although less pronounced in comparison with continuous fibers, toughening mechanisms such as fiber/matrix interface debonding, crack deflection, fiber bridging or even fiber pull-out occur in many fiber-matrix combinations. The strain-to-failure, fracture toughness and Weibull moduli are improved in general, compared to the monolithic matrix. Carbon fiber reinforced SiC composites are currently the most developed SF-CMCs, but also carbon fiber reinforced UHTCs and all-oxide CMCs show an advanced development status. Emerging areas still remain in the theoretical description of the toughening mechanisms, the target-oriented fiber alignment, the automation of the manufacture processes and the applicability of additive manufacturing methods.

Introduction

Ceramic matrix composites (CMCs) continue to attract attention for several engineering applications based on the highly attractive combination of properties they offer, such as high stiffness, fracture toughness and corrosion resistance together with a new range of functionalities for specific applications (Chawla, 2019) (Fig. 1). It is well-known that composites are a combination of two materials with different but complementary physical and chemical properties. Composites are designed to obtain better properties than ordinary (one-phase) materials due to effective interaction between the constituents.

Within the wide spectrum of CMCs, glass and glass-ceramic matrix composites (GMCs and GCMCs, respectively) represent a very important class of materials, since they offer attractive properties for a range of specific applications in which other materials cannot be used or are difficult to be applied. Regarding GMCs, due to the intrinsically low fracture toughness of the glass matrices ($< 1 \text{ MPa m}^{0.5}$), the reinforcement must be able to provide a significant improvement in the resistance to crack propagation, effectively acting as toughening elements (Boccaccini, 2006). On the other hand, glasses also have several unique characteristics that favor their application as matrices in some specific fields, e.g., its low viscosity at temperatures of 800–1400°C makes it possible to manufacture the material at substantially lower densification temperatures and with more intricate shapes than is possible with polycrystalline ceramics. Moreover lower processing temperatures lead to reduction of the possible degradation of the filler (reinforcement) in the course of composite fabrication (Chainikova *et al.*, 2014).

GCMCs use glass-ceramic materials as matrices taking advantage of their higher mechanical properties compared to glasses. Glass-ceramics are a special group of materials whereby a glass matrix is crystallized to different crystalline phases under carefully controlled heat-treatment conditions (Allix and Cormier, 2019; Kothiyal *et al.*, 2012).

The chapter aims at giving an up-to-date overview of glass and glass-ceramic matrix composites employed for advanced applications. It has evolved from previous overviews on the same topic (Boccaccini, 2006; Roether and Boccaccini, 2006), however with considerably updated information. General aspects of composite properties, e.g., mechanical behavior, thermal shock resistance and chemical stability to aggressive agents are presented. Part I of the chapter includes three sections. The first section provides a classification of the matrices and reinforcements used for GMCs and GCMCs highlighting the main

Fig. 1 Main application fields of glass and glass-ceramic matrix composites.

characteristics/properties of these materials. This section deals with the design and formulations of such composites adopted to achieve the required standard for various applications. Properties such as thermal expansion coefficient, chemical stability, density and mechanical resistance are discussed. Toughening mechanisms in GMCs and GCMCs are covered in the following section while the third section will consider the typical manufacturing processes for GMCs and GCMCs. Part II reviews the most important fields of application of this kind of composite materials. Previous work concerning applications of GMCs and GCMCs in aerospace, medicine, solid oxide fuel cells (SOFCs), electronic devices and in structural composites is presented and discussed.

Composite Constituents

The Matrices: Glasses and Glass-Ceramics

Glasses are non-crystalline (amorphous) solids, typically transparent or translucent, obtained by rapid cooling of a melt to room temperature, which as result of the increase of viscosity exhibits the mechanical properties of a solid (Shackelford and Doremus, 2008). The production of glasses involves three types of oxides, which are called formers, fluxes, and stabilizers (Musgraves *et al.*, 2019; Bansal and Doremus, 2013). Most technical glasses are based on silica (SiO_2) as glass former oxide.

Considering the glass production worldwide, soda-lime glasses represent most (approximately 90%) of the production (Musgraves *et al.*, 2019), taking into account that pure silica, due to its elevated melting temperature (1723°C), is challenging to produce and difficult to shape in technically relevant structures (Bansal and Doremus, 2013). For this reason, “soda”, or sodium carbonate (Na_2CO_3), is added to lower the glass-transition temperature (Bansal and Doremus, 2013). However, soda makes the glass water-soluble, which is usually undesirable. To avoid the increase of glass solubility following the addition of sodium carbonate, “lime” (CaO) is incorporated to provide better chemical durability. Other glass formers used to produce technical glasses are boric oxide (B_2O_3) and phosphorus pentoxide (P_2O_5). An important class of technical silicate glasses are borosilicate glasses which are based on silica and boron trioxide as glass-formers. Borosilicate glasses show very low coefficients of thermal expansion ($\approx 3 \times 10^{-6} \text{ K}^{-1}$ at 20°C), which make them resistant to thermal shock in comparison to other glasses such as soda-lime glass (Musgraves *et al.*, 2019). Borosilicate glasses are used in numerous industrial sectors, including electronics, cookware, laboratory ware and scientific equipment as well as in optics, aquarium heaters, and thermal protection systems. Special properties of borosilicate glasses include high strength, chemical durability and heat resistance (Madheshiya *et al.*, 2018) which has enabled their use in very special applications as for example in the coating of the thermal insulation tiles on the Space Shuttle (Space Shuttle Orbiter Systems, 1988). Furthermore, borosilicate glasses are used for immobilization of radioactive wastes (Zhu *et al.*, 2020) and as glass tubing in TIG welding torch nozzles (Muñoz-Sánchez and Cabezas, 2018). Given their outstanding thermo-mechanical properties, borosilicate glasses are interesting matrices to develop GMCs (Boccaccini *et al.*, 1994).

Glasses show intermediate values of elastic modulus, normally in the range of 60–90 GPa, while the elastic modulus of typical reinforcements, especially fibers, is usually higher than 200 GPa (Bernardo, 2011). This difference in stiffness between matrix and reinforcement is relevant for the design of GMCs, since this elastic mismatch determines if effective load transfer may occur between the matrix and the reinforcement (Bernardo, 2011). In contrast, for polycrystalline CMCs, a load transfer mechanism is less effective because the values of elastic modulus of matrix and reinforcement are similar.

The properties of glasses such as their characteristic temperatures or the thermal expansion coefficients may be changed by adjusting their chemical composition. In fact, tailored and well-designed compositions are crucial to convert glass matrices into glass-ceramics matrices: densification and crystallization of a glassy matrix lead to the achievement of higher creep resistance and higher elastic modulus (Bernardo, 2011; Bansal and Doremus, 2013). Other properties lead to materials with extended functionalities: the transparency enables the use of glasses in optical applications (Zhang *et al.*, 2006; Calvez, 2014), the doping with rare earth elements may lead to semiconducting behavior, permitting their use in electronics (Dey *et al.*, 2016), antibacterial properties enable their use in the biomaterials sector (Nakamura *et al.*, 2021) and chemical inertness motivates their use as safe matrices for inclusion of hazardous wastes (Pace *et al.*, 2005).

Each glass exhibits a characteristic softening point, which depends on its composition: glasses can deform and flow when their viscosity decreases at moderately high temperatures. In this state, they can infiltrate fiber assemblies without causing mechanical damage, thus facilitating composite fabrication. Glass matrices can achieve full density, especially if the processing is carried out by application of hot pressing of glass powders mixed with the reinforcing phase (Bansal and Doremus, 2013). Furthermore, glasses are considered economically attractive. This is because the cost of the raw materials employed to manufacture glass matrices are relatively low and the materials are widely available, especially in the case of glasses of silicate compositions. Moreover, it should be noted that recycling generates a large amount of crushed glass. In this case, the production of glass matrices is cost-effective since neither refining of a glass melt nor annealing are usually needed (Kothiyal *et al.*, 2012; Musgraves *et al.*, 2019).

A particular class of glasses are bioactive glasses, developed for the first time by Hench *et al.* in 1969 (Hench, 2006), representing a group of bioreactive materials that are able to bond to bone tissue in physiological environment. These amorphous silicate-based materials have the potential to interact with the human body establishing a bond to bone and/or repairing damaged bone and soft tissues (Ratner, 2019). The main constituents of standard silicate bioactive glasses are SiO_2 , CaO , P_2O_5 , and Na_2O , in proportions different from those of stable soda-lime silica glasses used in non-biologic applications. Bioactive glasses can be transformed into glass-ceramics by changes in the starting formulations and by addition of nucleating agents, inducing the

formation of crystals within the glass matrix during sintering. Furthermore, several studies have shown the fabrication of bioactive glass-based GMCs by the addition of different ceramic fillers.

Glass-ceramics

Glass-ceramics (GCs) derive from the crystallization of a glass, implying the formation of several crystalline phases within a matrix of residual amorphous material. The resulting structure combines the properties of glasses with the benefits of crystalline phases (Deubener *et al.*, 2018; Karmakar, 2017). Briefly, the glass is subjected to a thermal treatment that induces nucleation and crystallization of crystals in the remaining glass (Allix and Cormier, 2019). Glass-ceramics range from transparent to opaque depending on the amount of crystalline and glassy phases. Modifying the chemical compositions and the heat treatment schedules, the properties of glass-ceramics may be tuned to satisfy demanding requirements in several applications. The combination of knowledge about glass-ceramic systems and experimental data available in literature plays a key role in the design of GC matrices with the correct glassy and crystalline phase contents to achieve the desired properties and final product quality. The constituting chemical elements and their percentage in the composition regulate the glass-ceramic properties (Pannhorst, 1997). The compositions are tailored by adding to the base (parent) glass specific mineralizers or oxides able to give finely dispersed crystalline phases upon controlled thermal treatments. Holand and Beall (2012) classified glass-ceramic materials based on their chemical composition, as alkaline and alkaline earth silicates, aluminosilicates, fluorosilicates, silicophosphates, iron silicates, and phosphates. Another useful classification of glass-ceramics divides them into oxide and non-oxide categories (Holand and Beall, 2012; Karmakar, 2017). Oxide glass-ceramics include silicate, phosphate, borate and materials based on GeO_2 .

A wide variety of glass-ceramic materials is available with different microstructures and properties, which are associated with the combination of amorphous and crystalline phase properties. To attain specific properties, the right combination of chemical composition and an optimal heat treatment cycle to favor the process of nucleation and crystal growth are required (Holand and Beall, 2012). In general, some glass-ceramics can present almost close to zero coefficient of thermal expansion, high fracture toughness, high resistance toward impact and other unique characteristics (Bach, 2005). Glass-ceramics resulting from the crystallization of β -eucryptite and β -spodumene, as an example, are characterized by low coefficients of thermal expansion (CTE) (Bach, 2005; Arcaro *et al.*, 2017). Such low CTE glass-ceramics are materials of choice for applications that require resistance to very rapid temperature changes (high thermal shock resistance), including heat exchangers, household cookers, cutting tools and precision optical instruments (Arcaro *et al.*, 2017). Another interesting family of glass-ceramics involves those based on perovskites and spinel structures (Dugué *et al.*, 2019). These show a satisfying refractoriness, good optical, electrical and mechanical properties which make them useful for example as constituents of solar panels, screens with liquid crystal display and magnetic disks (Manzani *et al.*, 2019; Walas *et al.*, 2019; Tarafder *et al.*, 2016). Mullite crystallization offers the possibility of producing materials with high chemical resistance and high temperature capability (Fathi and Johnson, 2016; Duminis *et al.*, 2017). High mechanical resistance can be achieved also by the crystallization of canasite (Fu *et al.*, 2017). Sometimes it is difficult to control functionally opposite properties such as a high workability with sufficient hardness, a high chemical resistance in an environment rich in alkaline elements/oxides or turning an inert glass-ceramic into a bioactive glass (Holand and Beall, 2012). GCs can also be used for waste encapsulation (Rawlings *et al.*, 2006; Stoch *et al.*, 2018; McCloy and Goel, 2017). Glass-ceramic materials can be also manufactured from rocks, e.g., basaltic rocks, to obtain high chemical and wear resistance materials. In general, GCs are outstanding systems for the development of matrices for composites.

The Reinforcements

Ceramic particles, chopped fibers, whiskers and platelets are the most commonly used discontinuous reinforcements in glass and glass-ceramic matrices (Roether and Boccaccini, 2006). As particulate reinforcing phases, alumina, SiC, silica, zirconia, titania, mullite, silicon nitride, cordierite, chromia, boron nitride, aluminum nitride and thoria particles have been used (Arcaro *et al.*, 2017; Roether and Boccaccini, 2006). For example, zirconia particles have been utilized in glass and glass-ceramic matrices to improve their mechanical properties. The effects of zirconia particles on densification, flexural strength and fracture toughness of GCs have been reported for lithium aluminosilicate (LAS) GCs (Choi and Ahn, 1997), for mica-based GCs (Montazerian *et al.*, 2008a) and for mica-apatite compositions (Montazerian *et al.*, 2008b). The reinforcement of apatite-wollastonite GCs with alumina particles is reported in (Park *et al.*, 2010), which led to an interesting system for biomedical applications, especially for the repair and replacement of natural bone.

Metallic second phases as nickel particles or stainless steel chopped fibers have been also investigated as reinforcing phases in glass and GC matrix composites where specially the plastic deformation of the metallic phase is used to impart increased fracture toughness to the brittle matrices. Typical metals reported in literature and used as reinforcement in GMCs and GCMCs are stainless steel and other alloys (e.g., Fe-Ni-Co) as well as elemental metals such as Ag, Al, Au, Cu, Fe, Mo, Nb, Ni, Ti, Pb, and V and intermetallics (e.g., Ni_3Al). Metallic inclusions in the form of particles, flakes, wires and fibers have been used in GMCs and GCMCs (Roether and Boccaccini, 2006; Riaz *et al.*, 2020; Rai *et al.*, 2020; Miller and Misture, 2010).

Dispersion-reinforced composites, despite the limited enhancement in fracture toughness they provide with respect to fiber-reinforced GMCs and GCMCs, are used in several industrial applications due to their low-cost manufacturing and the possibility to develop complex mixtures with different functionalities (Roether and Boccaccini, 2006).

The use of long (continuous) fibers to reinforce glass and glass-ceramic matrices was first proposed more than 50 years ago, as discussed elsewhere (Boccaccini, 2006). Fibrous reinforcements (mainly carbon and SiC fibers) can strengthen the glass/glass ceramic

matrix leading to a remarkable improvement of the fracture strength and toughness in comparison to the unreinforced matrices. The use of fibers, in fact, allows the development of composites with enhanced fracture toughness (of up to 30 MPa m^{1/2}) and outstanding fracture tolerance at service temperatures up to about 1500°C (depending on the type of matrix) (Bernardo, 2011). GMCs and GCMCs with continuous fiber reinforcement have been proposed for structural applications in energy conversion systems and in the automotive and aerospace sectors as they are lightweight materials with high thermal capability and stiffness. Such composites find applications also in ballistic protection panels, in chemical plants, metallurgical processes, thermal protection, precision and micro-engineering and special machinery.

The incorporation of second phases in glasses and glass-ceramics has been also explored to obtain composites with specific functionalities, e.g., such composites were not only developed with the purpose to improve the mechanical properties of the matrix. Some examples of such functional composites are: GMCs for multilayer ceramic circuit boards in microelectronic packages (El-Kheshen *et al.*, 2009; Marques *et al.*, 2010), thick film resistors (Li *et al.*, 2018; Totokawa *et al.*, 2009), GMCs and GCMCs containing ferroelectric phases (e.g., lead zirconate titanate, barium titanate) (Liu *et al.*, 2014; Harizanova *et al.*, 2020; Rahangdale and Deshpande, 2019), semi-conductor nanoparticles (e.g., CdS, ZnSe, etc.) (Yuryeva *et al.*, 2020; Han *et al.*, 2018; Xue *et al.*, 2020; Janbandhu *et al.*, 2019a,b), ZnO-glass composite varistors (Feng *et al.*, 2020; Biswas *et al.*, 2019), silica composites incorporating carbon particles (Ott *et al.*, 2020), metallic nanoparticles/nanoclusters and a variety of other GMCs for optical (Li *et al.*, 2019; Veber *et al.*, 2019; Wei *et al.*, 2019), biomedical (Menazea and Abdelghany, 2020), decoration (Rostampour and Eavani, 2020) and high-dielectric strength applications (Fuentes *et al.*, 2019; Liu *et al.*, 2019; Prabhu *et al.*, 2020). Moreover cordierite GCMCs (Jiang *et al.*, 2019) and oxynitride GMCs (Baron *et al.*, 2000) incorporating SiC nanoparticles (5–10 vol%) have been developed. More recently, carbon nanotubes have been used as reinforcing elements in GMCs and GCMCs (Ramasamy *et al.*, 2019; Patil *et al.*, 2020), including fused silica (Okawara *et al.*, 2019), borosilicate glass (Boccaccini *et al.*, 2007, 2005; Thomas *et al.*, 2009; Chu *et al.*, 2008) and cordierite glass-ceramic (Salahi *et al.*, 2019) matrices. GMCs have been also developed incorporating organic phases in order to achieve novel functional properties (Avetissov *et al.*, 2018; Roether and Boccaccini, 2006).

Laminated reinforced composites are especially designed to increase the impact resistance and/or the flexural strength. For example, glass-ceramic substrates based on the LiO₂-ZrO₂-SiO₂-Al₂O₃ (LZSA) system have been manufactured by laminated object manufacturing (LOM) for microelectronic packages using water-based cast tapes (Gomes *et al.*, 2011). Other applications include the fabrication of laminated bilayers of lithium ion conducting glass-ceramics and polymer electrolytes for the development of composite solid electrolytes for Li ion batteries (Tenhaeff *et al.*, 2012).

Analysis of the literature indicates that, in general, GCMCs with discontinuous reinforcing phases have an important advantage over GMCs reinforced with continuous fibers: low cost of raw materials and simple production methods (Chainikova *et al.*, 2014) even if the increase in mechanical properties is not as pronounced as for continuous fiber reinforcement. Indeed in recent years there has been an increase in the development of GMC and GCMC systems with discontinuous phases aiming at obtaining systems with specific functional properties (Chainikova *et al.*, 2014).

Toughening Mechanisms in GMC and GCMC

In GMCs and GCMCs, like in most ceramic matrix composites, the interactions between cracks and the dispersed phase are basically intended to increase the fracture toughness (K_{IC}). A reduction in the scattering of strength data is achieved, however, only if cracks encounter a progressive resistance to their propagation, according to a substantial dissipation of fracture energy (Evans, 1990). Numerous previous studies have considered toughening mechanisms in GMCs and GCMCs, as summarized in this section.

In a GMC an increase of critical value of the strain energy release rate (G_c) ($G_c \sim K_{IC}^2/E$, with E being the elastic modulus) may arise from the bowing of a crack front between dispersed particles in a matrix, as found when Ni and alumina particles are dispersed in glass matrices (Stett and Fulrath, 1968; Lange, 1971). However, the effect of inclusions is improved if the crack front deviates from the original plane, in a condition of ‘crack deflection’, according to a system of internal stresses. These stresses are caused by the thermo-elastic mismatch between constituents, upon the cooling of composites from the manufacturing temperature. The out-of-plane deflections are enhanced especially when inclusions with high aspect ratio are used, such as whiskers (Gadkaree and Chyung, 1986) (Ye *et al.*, 2001) or disc-shaped Al₂O₃ or SiC mono-crystals (platelets) (Chaim and Talanker, 1995) (Verma *et al.*, 1995; Ye *et al.*, 2003; Boccaccini, 1994; Boccaccini and Trusty, 1996; Todd *et al.*, 1999).

A much more substantial dissipation of fracture energy derives from the inclusion of continuous, aligned fibers (Nicolais *et al.*, 2012) (see Table 1; Bernardo, 2011) by means of a careful control of the matrix-fiber interface. In fact, a too weak interface would not allow any load transfer, while a too strong interface would induce some toughening only by crack deflection.

Debonding of fibers, when a crack approaches fibers, implies remarkable energy dissipation by itself; the dissipation being further enhanced when fibers are partially pulled out. The amount of energy involved in debonding and pull-out is proportional to the strength of the fiber and to the so-called *critical length* (l_c) (Matthews and Rawlings, 1994), given by the equation:

$$l_c = \frac{\sigma_{f, fail} \cdot D}{2\tau}$$

where $\sigma_{f, fail}$ is the fiber failure stress, D is the fiber diameter and τ is the interfacial shear stress. The excellent fracture toughness of about 35 MPa m^{0.5}, accompanied by a bending strength exceeding 800 MPa (Nicolais *et al.*, 2012), found for example in carbon fiber-reinforced glasses, basically derives from the suitable interfacial bonding (low interfacial shear stress, long critical length).

Table 1 Examples of fibrous reinforcements for glass and glass-ceramic matrix composites

Material	Diameter (μm)	Density (g/cm^3)	E (GPa)	Ultimate tensile stress (GPa)	Thermal expansion coefficient (10^{-6} K^{-1})
B monofilament	100–200	2.5	400	2.75	4.7
SiC monofilament	140	3.3	425	3.45	4.4
Carbon yarn	7–10	1.7–2.0	200–700	1.4–5.5	–0.4 to –1.8
Thornel 300 ^a [39 vol%]			234 [127]	2.93 [0.71]	
HM ^a [54 vol%]			350 [180]	2.70 [0.62]	
GY-70 ^a [58 vol%]			516 [275]	2.07 [0.68]	
P-100 ^a [54 vol%]			654 [332]	2.07 [0.68]	
SiC yarn (Nicalon, Nippon Carbon Co., Japan)	10–15	2.55	190	2.4	3.1
FP alumina yarn (Du Pont, Wilmington DE)	20	3.9	380	1.4	5.7
Alumino-silicate yarn (Nextel 312, 3M Co., St. Paul, MN)	10	2.5	150	1.7	

^aExamples of fibers introduced in unidirectional carbon-fiber-reinforced borosilicate glass matrix composites; between square brackets are reported the fiber loading and the composite properties, in terms of elastic modulus and ultimate tensile strength.

Interestingly, the relatively weak glass-carbon bonding also explains the success of polymer-derived SiC fibers as reinforcing elements in borosilicate glass (Prewo and Brennan, 1980) and lithium alumino-silicate (LAS) GC matrices (Brennan and Prewo, 1982; Prewo, 1986, 1987). A thin (10–50 nm) carbonaceous layer, promoting a significant fiber pull-out effect, is the result of a solid-state reaction between SiC and oxygen from the glass matrix during the composite fabrication process.

Another phenomenon implying substantial energy dissipation is the plastic deformation of metal inclusions, ideally forming ductile ligaments in the proximity of the crack tip. Although widely studied in the context of GMCs and GCMCs (Green *et al.*, 1979; Powell *et al.*, 1980; Biswas, 1980; Krstic *et al.*, 1981; Waku *et al.*, 1997; Dlouhy *et al.*, 1997), this particular toughening mechanism has significant technological and theoretical constraints, to be effective. To prevent the melting of inclusions, composites should be manufactured with glasses with relatively low sintering temperatures, such as calcium-phosphate glasses (enabling also low temperature crystallization, for glass-ceramic matrices), or PbO and ZnO-rich solder glasses (Pernot and Rogier, 1993; Vaidya and Subramanian, 1990; Claxton *et al.*, 2002). To prevent crack deflection, the differences in terms of both thermal expansion coefficient and elastic modulus of the constituents should be minimized (Krstic *et al.*, 1981). Finally, to prevent debonding, the glass-metal interface should be strong, which is typically achieved by promoting the surface oxidation of metal particles (Krstic *et al.*, 1981; Bernardo *et al.*, 2003).

Even considering the mentioned constraints, Al inclusions were found to lead to a remarkable effect (toughness and critical energy release rate exceeding $6 \text{ MPa m}^{0.5}$ and 600 J m^{-2} , respectively) (Krstic *et al.*, 1981). The toughening was not particularly enhanced by the replacement of particles with short fibers, or ribbons (Vaidya and Subramanian, 1990). On the contrary, more spectacular effects were found with long stainless steel and Ni-based alloy filaments or with stainless steel bidimensional mats in glass and glass-ceramic matrices (work of fracture up to 50 kJ m^{-2}) (Donald and Metcalfe, 1996; Boccaccini *et al.*, 1997).

A final, very important dissipative phenomenon corresponds to the transformation of a secondary phase, as found in ceramic composites embedding metastable tetragonal zirconia nano-crystals. The latter phase was effectively introduced in both sol-gel derived glasses (Nogami and Tomozawa, 1986) and more conventional calcium phospho-silicate glasses crystallizing to mica and mica-apatite (Montazerian *et al.*, 2008b). In these systems, the crack propagation is hindered by compressive stresses around the same crack front, in turn induced by the tetragonal-to-monoclinic transformation – with volumetric expansion – of the zirconia inclusions. Composites exhibiting fracture toughness values up to $5 \text{ MPa m}^{0.5}$ have been developed. Less substantial effects may arise from other inclusion transformation mechanisms, such as the stress-induced alignment of polarization domains in piezo-electric particles, as found for PZT (lead zirconate titanate) particles embedded in a lead containing glass (Boccaccini and Pearce, 2003).

Manufacturing Techniques

GMCs and GCMCs are characterized by the relatively straightforward manufacturing technologies required for their production (Boccaccini, 2006). An important advantage of glass and glass-ceramic matrices is that their processing temperatures are considerable lower than those required for polycrystalline ceramics. The capacity of glass to flow (much like polymeric resins) at moderate temperatures is exploited in different fabrication strategies to produce GMCs and GCMCs.

Powder Technology

Powder technology is one of the most extensively employed techniques for the manufacturing of GMCs and GCMCs because it is a simple and economically efficient method which permits the use of standard processes used in the ceramic industry: mixing of

Fig. 2 Manufacturing steps in the powder technology process for fabrication of GMCs and GCMCs.

powders, compaction and sintering. The main steps of the process are shown schematically in [Fig. 2](#) ([Chainikova et al., 2014](#); [Roether and Boccaccini, 2006](#)). A non-homogeneous distribution of the dispersed phase due to the agglomeration of filler particles may lead to structural defects, such as voids and cracks ([Chainikova et al., 2014](#)). To avoid this, it is important to adjust the granulometric composition of the powders and to use wet mixing in aqueous or organic solvents with addition of suitable binders (e.g., polyvinyl alcohol) and the simultaneous application of ultrasonic or magnetic agitation to break up agglomerates. From an economic point of view, the simplest process includes sintering without compaction of the powder mixture at temperatures in the range from T_g to T_f of the glass matrix. In this case, the composite is densified via softening of the glass phase by the viscous flow mechanism. However, this method can be used only at low filler contents (up to 15%) ([Chainikova et al., 2014](#)). [Eberstein et al. \(2009\)](#) used $\alpha\text{-Al}_2\text{O}_3$ particles as rigid inclusions in alumo-borosilicate glass preparing composites via softening of the glass phase by the viscous-flow mechanism. An improved processing method for fabricating multiwalled carbon nanotube/GC nanocomposites based on vanadium doped silicate glass matrices has also been reported ([Giovanardi et al., 2010](#)).

Hot-pressing allows to obtain a higher degree of densification at high filler content (up to 90%) ([Chainikova et al., 2014](#)), because densification occurs under pressure (between 5 and 20 MPa) in a mold. Hot pressing is, however, a relatively expensive method and shows limitations when intricate geometric composite shapes are required ([Chainikova et al., 2014](#)).

Slurry Infiltration and Hot-Pressing

One of the most used approaches for manufacturing fiber-reinforced GMCs and GCMCs is based on the hot-pressing of powder infiltrated fiber preforms or fabric lay-ups. Individual fibers (or fiber tows) and fiber bodies are usually coated by matrix powder using a slurry (slurry dipping method). The slurry is composed of the glass powder, an organic binder, and a liquid carrier which is usually water, alcohol or a mixture of both. The design of the slurry is a key step in this fabrication process as it will impact the quality of the “green body” (e.g., the material before densification heat treatment). The development of the slurry must include the optimization of the powder content, particle size distribution, type and amount of binder, as well as proper selection of the liquid. For example, using a glass powder with particle size smaller than the fiber diameter will lead to better impregnation of the fiber bodies and thus it will reduce residual porosity. The infiltration of particles into fiber mats can be further improved by adding wetting agents to the slurry. Densification occurs during the hot-pressing stage when temperature is high enough to enable viscous flow of the glass particles into the pores between individual fibers. Hot-pressing enables the application of uniaxial pressures (in the range 10–20 MPa) to facilitate viscous flow after the temperature has reached the softening point of the glass, leading to highly dense (almost pore free) GMCs and GCMCs. Hot-pressing has been a common technique employed to fabricate borosilicate GMCs reinforced with SiC (Nicalon® type) fibers ([Boccaccini, 2006](#)). In the case that a glass-ceramic matrix is needed, a crystallization thermal treatment of the glass matrix after densification can be performed. [Xia et al. \(2018\)](#) reported the manufacturing of laminated $\text{SiC}_{\text{NW}}\text{-C}_f/\text{LAS}$ matrix composites by this method. Recently, a series of carbon fiber reinforced lithium aluminosilicate GC matrix composites (C_f/LAS) has been produced by the slurry infiltration coupled with hot pressing method ([Xia et al., 2015](#); [Ma, et al., 2020](#); [Wang et al., 2019](#)).

Sol-Gel, Colloidal Routes and Electrophoretic Deposition

The sol-gel method has been used to develop silicate matrices starting from metal alkoxide solutions or colloidal sols as precursors ([Boccaccini, 2006](#)). The precursors are hydrolyzed, polymerized into gels, and subsequently dried and heat-treated to obtain silicate glasses. For fabrication of composites (fiber reinforced) the fibers are immersed in a sol to deposit a thin silica gel layer on the fiber surfaces. A heat treatment at temperatures in the range 100–200°C is first required to remove the liquid from the gel and a second heat-treatment at higher temperatures (300–500°C) is necessary to burn out organic residues. Multiple infiltration cycles

may be required to achieve sufficient densification after which the composite sample is dried and heat-treated at high temperatures to obtain the final glass or glass-ceramic matrix.

The densification can occur by pressureless sintering or by hot-pressing. There are several advantages of the sol-gel method over powder processing (slurry infiltration) that can be highlighted. Thus, better fiber infiltration can be achieved that can facilitate densification even by pressureless sintering or by applying lower hot-pressing temperatures. This less aggressive fabrication process will have an extra beneficial effect as it will limit structural damage to fibers (Boccaccini, 2006). The sol-gel processing method is also advantageous when complex fiber structures are used as reinforcement as it enables a more effective infiltration of such fiber preforms that powder based slurry infiltration. The sol-gel method has some drawbacks however, in particular due to the large shrinkage that sol-gel derived matrices exhibit due to the presence of liquid in the starting green structure which must be removed in the drying and densification stages. Such large shrinkage usually leads to the development of microcracks which are detrimental to the mechanical properties of the resulting glass matrices. In addition, the sol-gel technique requires a large number of infiltration/drying cycles as mentioned above, which makes the process time-consuming and expensive. Sol-gel processing has been reported in the fabrication of borosilicate, and lithium- (LAS), magnesium- (MAS), barium- (BAS), calcium- (CAS) and sodium- aluminosilicate matrices (Boccaccini, 2006). Wang *et al.* (2011) report the manufacturing of $\text{CaO-B}_2\text{O}_3\text{-SiO}_2$ glass/ CaSiO_3 (CBS/CS) matrix composites via sol-gel processing routes. Moreover, porous composites based on Si_3N_4 and sol-gel derived BG have been fabricated and characterized (Frajkorová *et al.*, 2015). The sol-gel based fabrication of bioactive GCMCs for dental applications is presented by Chatzistavrou *et al.* (2012), showing the development of microporous GCs for applications as coatings for dental ceramics.

Electrophoretic deposition (EPD) has been shown to be a versatile and attractive technique to infiltrate fiber preforms with nanoparticles of the matrix material for fabricating composites (Boccaccini *et al.*, 2001). After EPD infiltration of fiber preforms, pressureless sintering or hot-pressing is employed to densify the matrices and thus obtain mechanically robust composites. Numerous GMCs and GCMCs incorporating 2-dimensional fiber mats as reinforcement have been fabricated by EPD over the years (Boccaccini, 2006). More recently, EPD of mesoporous bioactive glass on glass-ceramic foam scaffolds for bone tissue engineering has been introduced (Fiorilli *et al.*, 2015).

Polymer Infiltration and Pyrolysis (PIP)

In the PIP process, a fiber preform is combined with an organic material that can be converted to a ceramic on heat treatment (pyrolysis). Usually fiber preforms are infiltrated multiple times with a liquid organic precursor that can be converted by pyrolysis to a ceramic. Instead of a conventional thermoset resin (e.g., epoxy) used to make polymer matrix composites, an organometallic polymer is used. Usually multiple and time consuming infiltration and pyrolysis cycles are required to obtain dense composites, which results in a relatively expensive process. Silicon oxycarbide glasses and glass-ceramic materials (SiOC) have been reported for advanced structural and functional applications (Stabler *et al.*, 2018). The chemical and phase compositions of SiOC glasses and glass-ceramics obtained by PIP strongly depend on the heat treatment parameters such as pyrolysis temperature, heating rate, dwell time and atmosphere. Three-dimensional braided carbon fiber reinforced silicon oxycarbide composites have been developed by multiple polysiloxane impregnation and pyrolysis cycles (Ma *et al.*, 2005). Moreover, basalt fiber reinforced SiOC-matrix composites have been also manufactured by PIP (Weichand and Gadow, 2015). Additive manufacturing techniques have been also developed showing high potential for the processing of polysiloxanes to fabricate complex-shaped and miniaturized parts.

Powder-Bed-Based Technologies: 3-D Printing and Selective Laser Treatment

Powder-based indirect additive manufacturing technologies involve the sequential deposit of thin layers of powder, followed by applying selective laser treatments or by ink-jetting a liquid binder (Cannio *et al.*, 2019). Three-dimensional printing (3DP) is a powder based additive manufacturing (AM) method which is commonly used to fabricate complex structures (Sun *et al.*, 2017). Post-processing including binder removal and sintering is required. In comparison to other AM technologies, such as fused deposition modeling (FDM) and stereolithography (SL), 3DP can be applied to a variety of materials. For example, 3DP has been applied to obtain hydroxyapatite/apatite-wollastonite GCMCs (Suwanprateeb *et al.*, 2009) and 13–93 bioactive glass-hydroxyapatite (HAp) composites (Winkel *et al.*, 2012). In another study, the powder-based three-dimensional (3D)-printing of wollastonite (CaSiO_3)-based silicate bioceramic parts has been described (Zocca *et al.*, 2015).

Alternative Fabrication Methods

Other techniques suggested to fabricate complex shaped GMC and GCMC articles are the matrix transfer molding and injection molding techniques (Bernardo, 2011). In the first method, fibers are wound on a mandrel inserted in a shell and glass is forced to fill the gap between the mandrel and the shell wall. This technique is suitable to manufacture thin-walled hollow tubes and similar shapes. In the injection molding method, glass powders, usually mixed with chopped fibers, are injected at high temperature into a mold cavity by applying uniaxial pressure. The technique leads to composites containing uniaxial oriented fibers. However the resulting composites are not particularly strong since the fiber orientation cannot be sufficiently controlled.

Another high temperature processing method for manufacturing unidirectional fiber reinforced GMCs in rod shape is pultrusion (Roether and Boccaccini, 2006). Glass impregnated fibers are passed through the nozzle of a crucible filled with molten glass. Possible degradation of the fibers is reduced by reducing the time of exposure to the molten glass. Another related processing technique for the manufacturing of rods or cylinders is extrusion (Roether and Boccaccini, 2006). In recent papers, extrusion has also been employed for the fabrication of transparent glass-ceramics functionalized by dispersed crystals (Liu *et al.*, 2018).

The sintering of GCMCs by microwave heating to improve the densification process has also been reported in literature (Chainikova *et al.*, 2014). Data reporting the sintering of SiO₂ powders, silicate gels, glass nanopowders, calcium-zirconium-silicate GCs, multilayer cordierite substrates and GCMCs based on glasses reinforced with SiC fibers or SiC whiskers have been presented (Chainikova *et al.*, 2014; Minay *et al.*, 2004).

Spark Plasma Sintering (SPS) has been shown to lead to high density GCMCs, increasing the mechanical properties of the resulting materials, compared with most standard hot-pressing techniques (Chainikova *et al.*, 2014). The SPS method has been tested in the fabrication of GCMCs based on BAS matrices (Ye *et al.*, 2008; Liu *et al.*, 2010), bioactive glasses (Jia *et al.*, 2011; Porwal *et al.*, 2015) and other silicate materials. Even if SPS is an important approach to obtain GCMCs from simple to complex shapes with full densification in a short time, SPS based synthesis as an alternative route to develop GMCs and GCMCs is still in its infancy.

Final Remarks

This chapter has summarized the field of glass and glass-ceramic matrix composites in its evolution in the last years covering the most popular matrices and reinforcements investigated and key properties achieved. GMCs and GCMCs have been fabricated by traditional techniques such as powder technology, slurry infiltration and sol-gel processing, with densification usually achieved by pressureless sintering or hot-pressing methods, but it is worth highlighting the introduction of novel methodologies such as electrophoretic deposition, SPS and 3D printing.

Applications of Glass and Glass-Ceramic Matrix Composites

Table 1 gives a summary of selected studies from the literature giving a short description of the manufacturing processes and properties of common glass matrix composites (GMCs) and glass-ceramic matrix composites (GCMCs) for various application fields. In the following paragraphs the typical applications of GMCs and GCMCs are discussed in more detail.

Aerospace

Advanced glass and glass-ceramic matrix composite materials have been developed for applications in the aerospace field. These materials should ensure reliability and their manufacturing processes must result in accuracy and precision of dimensions. Brakes, flaps, windows, lenses, panels, fuel components and sensors (speedometers, thermometers and altimeters) incorporate an specific amount of glass and glass composite materials (ElanTechnology, 2020). Other interesting structural applications include thermal protection systems in rocket exhaust cones, insulating tiles for space vehicles (e.g., the former space shuttle), missile nose cones and engine components (Wang *et al.*, 2017). Additionally, glass frit sealing is used to protect components against humidity and gas degradation. Hence being lightweight and having high temperature resistance, electrical insulation, high energy of ablation, resistance to corrosion, chemical stability, wear resistance, and ability to withstand vibration, are the typical properties that make these materials efficient and appealing for aerospace applications.

Mica glass-ceramics are well-known machinable ceramics, which exhibit zero porosity and, in general, are excellent insulators at high voltages, various frequencies and high temperatures. Mica GCs can be machined to complicated shapes and precision parts with ordinary metal-working tools. Their relatively high CTE matches those of most metals and sealing glasses (Zanotto, 2010). These unique properties of mica glass-ceramics make them suitable for use in different high-performance applications, including the manufacturing of aerospace components (Zanotto, 2010). Nevertheless these glass-ceramics suffer from their low hardness and insufficient mechanical strength (Montazerian *et al.*, 2008a). Many different methods can be applied to improve the mechanical properties of mica glass-ceramics, for example, through the addition of second rigid and strong phases forming GCMCs. However, this could lead to a reduction of the machinability of the material (Alizadeh *et al.*, 2008), unless the reinforcement phase itself has suitability for machining. The addition of other rigid and strong second crystalline phases such as fibers, whiskers and particles to the glass matrix can be effective. For example, different amounts of partially stabilized zirconia particles have been added to the starting composition to improve the mechanical properties (Montazerian *et al.*, 2008b; Gali, 2019; Ghaffari *et al.*, 2012).

The lithium aluminosilicate glass-ceramic family is one of the most studied systems to prepare materials with very low CTE. Eucryptite and spodumene are the most used and studied phases with these characteristics (García-Moreno *et al.*, 2011). Materials with a very low CTE are of great interest in aerospace applications (García-Moreno *et al.*, 2011). LAS glass-ceramics were originally developed for use in mirrors and mirror mounts of astronomical telescopes (Zanotto, 2010). However, LAS materials exhibit high brittleness. GCMCs of the aforementioned LAS matrix and a second phase of dispersed submicron alumina have been fabricated (García-Moreno *et al.*, 2011). Fig. 1(a) reports the investigated compositions, having different LAS/Al₂O₃ ratios, while Fig. 1(b) and (c) show FE-SEM images of the TLAS1 and TLAS2 compositions, respectively. The results obtained validated the possibility of designing composites with a very low CTE (e.g., the composites comprising 15.65 wt% alumina and 84.35 wt% of eucryptite gave the closest to zero CTE value) as well as improved mechanical properties.

The microwave heating of LAS GCs incorporating graphene has been reported (Benavente *et al.*, 2020). The composite exhibited high dielectric loss factor. García-Moreno *et al.* (2010) reported the pressureless sintering (conventional sintering) of LAS-nSiC nanocomposite with improved mechanical properties and excellent expansion behavior, which was achieved by means of controlling the crystallization of the matrix during sintering. In addition, LAS GCs reinforced with carbon nanofibres and alumina for controlled-thermal-expansion materials are reported in (Borrell *et al.*, 2012).

α -SiC/ β -Si₃N₄ co-reinforced barium aluminosilicate (BaAl₂Si₂O₈) (BAS) GCMCs have been prepared (Liu *et al.*, 2010). BAS has a very high melting point ($\sim 1760^\circ\text{C}$) and it can be used as a hot section component in propulsion systems after being reinforced with whiskers (Ye *et al.*, 2001), fibers (Bansal and Eldridge, 1998), platelets (Ye *et al.*, 2003b) or particles (Ma *et al.*, 2010). Indeed numerous studies have been reported on SiC particle and in situ β -Si₃N₄ grain-reinforcement of BAS GCMCs. Such composites achieved high chemical erosion resistance, good oxidation and thermal shock resistance and superior mechanical properties (Liu *et al.*, 2010). It has been demonstrated that SiC-reinforced BAS composites exhibit higher hardness and elastic moduli than β -Si₃N₄-reinforced BAS composites (Liu *et al.*, 2010). On the other hand, β -Si₃N₄-reinforced BAS composites were reported to

Table 1 Examples of applications with manufacturing process and properties of glass and glass-ceramic matrix composites

Application field	Matrix material composition	Reinforcement	Manufacturing process	Main properties			References
				Mechanical properties	Physical properties	Thermal properties	
Aerospace							
Retaining rings at hinge points, frame corners, spacers, reflectors and cavities in laser assemblies, electronics/semiconductors, precision coil formers, high voltage insulators	Mica-diopside machinable glass-ceramics	Y-PSZ powder	Powder technology (pressureless sintering) (Montazerian <i>et al.</i> , 2008a)	s_f^a : 50.91 $\pm$ 10.50 (matix) (Montazerian <i>et al.</i> , 2008a) s_f : 132.47 $\pm$ 13.8 MPa (composite with 15 wt% Y-PSZ) (Montazerian <i>et al.</i> , 2008a) K_{IC}^b : 0.8 $\pm$ 0.08 (Montazerian <i>et al.</i> , 2008a), 0.8 $\pm$ 0.2 (Gali <i>et al.</i> , 2018) (matrix) K_{IC}^c : 1.36 $\pm$ 0.07 (composite with 15 wt% Y-PSZ) (Montazerian <i>et al.</i> , 2008a), 3.6 $\pm$ 0.2 (composite with 20 wt% YSZ) (Gali <i>et al.</i> , 2018) HV ^d : 2.62 $\pm$ 0.36 (Montazerian <i>et al.</i> , 2008a), 2.0 $\pm$ 0.3 (Gali <i>et al.</i> , 2018) (matrix) HV: 4.35 $\pm$ 0.64 (composite with 15 wt% Y-PSZ) (Montazerian <i>et al.</i> , 2008a), 9.2 $\pm$ 0.5 (composite with 20 wt% YSZ) (Gali <i>et al.</i> , 2018) E^d : 73 $\pm$ 1.0 (matrix) (Gali <i>et al.</i> , 2018), E: 125 $\pm$ 5.0 (composite with 20 wt% YSZ) (Gali <i>et al.</i> , 2018)	Relative density (%): 97.2% (matrix) (Montazerian <i>et al.</i> , 2008a) — 92.4 (composite with 15 wt% Y-PSZ) (Montazerian <i>et al.</i> , 2008a)	CTE ^e : 5.07 $\pm$ 0.19 (composite with 20 wt% YSZ) (Gali, 2019)	(Montazerian <i>et al.</i> , 2008a) (Gali, 2019) (Ghaffari <i>et al.</i> , 2012) (Gali <i>et al.</i> , 2018)
Mirrors and mirror mounts of astronomical telescopes	Lithium aluminosilicate glass-ceramic family (LAS) with eucryptite and spodumene as main crystalline phases	Alumina	Pressureless conventional sintering and SPS	s_f : 163.8 $\pm$ 6.1 (Composite TLAS5 (84.35% LAS, 15.65 Al ₂ O ₃ Taimei)	Relative density (%): 98.8 (Composite TLAS5 (84.35% LAS, 15.65 Al ₂ O ₃ Taimei)	CTE (–150–450°C): –0.14 CTE (25–450°C): 0.56 (Composite TLAS5 (84.35% LAS, 15.65 Al ₂ O ₃ Taimei)	(García-Mor-eno <i>et al.</i> , 2011)
Mirrors and mirror mounts of astronomical telescopes	LAS	LAS + 20 vol% CNFs	SPS	s_f : 164.5 $\pm$ 5.4 K_{IC} : 2.28 $\pm$ 0.10	Relative density (%): 99.7	CTE (–150 to 450°C) –0.69 $\pm$ 0.05 CTE (25 to 450°C) –0.32 $\pm$ 0.05	(García-Mor-eno <i>et al.</i> , 2010)
Hot section component in propulsion systems	Barium aluminosilicate (BaAl ₂ Si ₂ O ₈)	α -SiC/ β -Si ₃ N ₄	SPS	s_f : between 493 $\pm$ 41 and 809 $\pm$ 55 K_{IC} : between 4.2 $\pm$ 0.7 and 7.9 $\pm$ 0.9 HV: between 12.2 $\pm$ 0.5 and 17.8 $\pm$ 0.6	All the compositions reached densities >99% of their theoretical		(Liu <i>et al.</i> , 2010)
SOFCs							
Sealings	BaO, Al ₂ O ₃ , SiO ₂ , CaO, TiO ₂ , ZrO ₂ , MgO, La ₂ O ₃ and B ₂ O ₃	Different ceramic fibers	Wet mixing	Good adhesion with the steel	–	–	(Haeng <i>et al.</i> , 2005)
Sealings	BaO, CaO, SiO ₂	20 wt% Ag particles and small amounts of Al ₂ O ₃ , B ₂ O ₃ , V ₂ O ₅ and ZnO	Wet mixing. Sealant deposition by screen printing.	Fracture stress 55 $\pm$ 6 MPa at room temperature; 25 MPa at 700°C and 7 MPa at 800°C			(Wei <i>et al.</i> , 2015)

exhibit higher flexure strength and fracture toughness, due to better load transfer and crack bridging mechanisms provided by the highly elongated β - Si_3N_4 grains. Thus, in the work of Liu *et al.* (2010), in order to obtain all the above mentioned properties in one composite, a co-addition of SiC and Si_3N_4 to the BAS matrix was intended. However, the effort to develop superior ternary phase composites to maximize the reinforcing effects by simultaneous addition of α -SiC and β - Si_3N_4 was only partially successful because the growth of β - Si_3N_4 grains was reduced by the presence of α -SiC, and thus the reinforcing effect of the inclusions was decreased (Liu *et al.*, 2010).

A multifunctional high-temperature GCMC containing aluminosilicate reinforcing fillers has been also developed (Solntsev, 2011). The composites were successfully tested for erosion resistance in aircraft engine jets (Solntsev, 2011).

The resistance of GCs to withstand ultra-high temperatures (i.e., above 2000°C) without significant damage in a strongly oxidative and ablative environment allows their use for extreme applications like the propulsion of rockets for hypersonic flight. Ultra-high temperature ceramic (UHTC) filled composites can be formed, for example, when GCs are used as matrices to protect carbon fibers (C_f) effectively protecting C_f/C matrix composites from oxidation by forming oxides with high melting points during application (Makurunje *et al.*, 2017). A coating that prevents oxygen permeation should be free of defects, continuous, and have a low rate of oxygen diffusion. Ren *et al.* (2014) developed several multiphase TaB_2 based GC coatings for C_f/C composites. It was found that the oxides of Ta-based boride/carbide in a borosilicate glass matrix increased the viscosity of the in-situ formed Ta-Si-O glass, reducing oxygen diffusion and therefore increasing the overall oxidation resistance of the C_f/C composites. Walker and Corral (2014) proved that the formation of ZrO_2 - SiO_2 GC coatings on C-C composite was responsible for enhanced oxidation protection. In the work of Li *et al.* (2018), a TaSi_2 - MoSi_2 - ZrO_2 -borosilicate glass (TMZG) coating was prepared on a carbon fiber-reinforced porous silicon oxycarbide (SiCO) composite for thermal protection.

SiC-fiber reinforced barium osumilite (barium-magnesium-aluminum silicate (BMAS)) GCMCs have been also developed for high temperature (T) applications (Dassios *et al.*, 2013). Infrared thermography (IRT) and acoustic emission (AE), two major non-destructive methodologies for evaluating damage in ceramic matrix composites (CMCs) for aerospace applications, have been used to characterize SiC-fiber reinforced BMAS laminates, confirming the suitability of such GCMC systems for aerospace technologies.

Solid Oxide Fuel Cells (SOFCs)

A common approach in the field of solid oxide fuel cells and batteries is the addition of powders and second phase materials (particles, fibers), in particular ZrO_2 , Al_2O_3 , yttria-stabilized zirconia (YSZ) or mixtures of these oxides, to develop ceramics with complex microstructures (containing two or more phases) via reaction sintering, with the aim of improving specific properties. For example it is a usual approach to use such composite systems to tailor the CTE in order to match the CTE values of all components in the SOFC stack, to enhance the mechanical and insulating properties of the final products and to achieve the required gas tightness.

Different glasses and glass-ceramics enriched with the inclusion of second phases to improve specific properties in SOFC technology have been reported. For example, compositions particularly suitable for solid oxide fuel cell sealants, based on glass matrices and different volume fractions of ceramic fibers have been reported in a US patent (Haeng *et al.*, 2005). Briefly, an organic component containing a porous ceramic fiber, a filler, a hardener and a plasticizer were added to a glass matrix in the system

$\text{BaO-Al}_2\text{O}_3\text{-SiO}_2\text{-CaO-TiO}_2\text{-ZrO}_2\text{-MgO-La}_2\text{O}_3\text{-B}_2\text{O}_3$. This addition of ceramic fibers can be used to avoid the undesired viscous flow of the glass matrix at high T. The patent (Russel *et al.*, 2010) describes the manufacturing of a glass seal with ZrO_2 and Al_2O_3 ceramic fibers in a mixture of both these oxides in different contents (1–60 wt% with respect to the GC matrix). A latex binder was added to the slurries to facilitate the extrusion of the composite. Finally, the green sealant was thermally treated to achieve densification of the structure during the SOFC stack assembly process. Moreover, a SOFC design having a glass composite seal has been reported (Anthony *et al.*, 2009). This glass composite seal includes fibers, powders, and/or beads of zirconium oxide, aluminum oxide, and YSZ to achieve the desired properties. The presence of a residual glass in the sealant is important to impart geometrical stability and to guarantee the required performance of the self-healing seal. Interesting designs of sealants for SOFCs with glass fibers or particle addition have been presented (Gross *et al.*, 2011; Zhao *et al.*, 2011; Le *et al.*, 2006; Taniguchi *et al.*, 2000; Lee *et al.*, 2007) and the performance of such composite sealants in terms of mechanical and sealing properties has been investigated. The results suggest that the fracture strength depends on the type and amount of the glass fiber used in the composite. Furthermore, the leakage rate was found to be related to the mechanical strength. Timurkutluk *et al.* (2019), for example, employed glass fibers and demonstrated that structures showing high bonding strength values can be obtained when a single glass fiber layer is located between two GC layers. Therefore glass fibers can be conveniently used as reinforcements for GCMC materials based on their relatively high strength, low density and low cost. The reinforced composites obtained will exhibit superior joining strength and high temperature sealing performance if the type of glass fiber is carefully selected. As suggested by Timurkutluk *et al.* (2019), further studies are required to investigate the influence of the addition of glass fibers on the kinetics of crystallization and the formation of new crystalline phases to better understand the effect of CTE mismatch between the fibers and other components of the SOFC. Fig. 2 shows a schematic diagram of a SOFC stack and a SEM cross-sectional image of the sealant in the design of Timurkutluk *et al.* (2019). Wei *et al.* (2015) improved the mechanical properties of a sealant in the BaO-CaO-SiO_2 ternary system by adding Ag particles and small concentrations of Al_2O_3 , B_2O_3 , V_2O_5 and ZnO. The tests performed on the annealed Ag reinforced GC sealant showed a lower average fracture stress and higher creep resistance compared to the as-sintered sealant: this positive effect on the mechanical behavior of the investigated composite was reported to be due to the incorporation and uniform distribution of Ag particles in the matrix and the reduction of the glassy phase during annealing.

Some attempts have been also made to establish the potential of natural silica sand, instead of commercially expensive materials, to be used as a future SOFC sealant (Hidayat *et al.*, 2017). The manufacturing process starts with a first step in which sand is washed, ball-milled and then heated at 1000°C for 1 h. Finally, the obtained powder is mixed with alumina powder at different percentages and treated at 1150°C and 1250°C . The main phases in the $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{CaSiO}_3$ composite are cristobalite (SiO_2) and wollastonite (CaSiO_3) with alumina (Al_2O_3) inclusions. The results suggest that the similarity of the CTE with the one of other stack components means that the material is attractive for use as sealant in SOFCs.

In a related study, Brochu *et al.* (2006) investigated the feasibility of adding YSZ powders to modify the crystallization, microstructure and properties (CTE, wettability) of two borate glasses containing Ba and Sr, respectively, used as sealants in electrolyte supported SOFCs. It was found that Ba-containing glass reacted with YSZ to form BaZrO_3 which led to a significant reduction of CTE. On the other hand, the reaction between the Sr-containing glass and YSZ during heating led to the formation of strontium zirconate. The measured CTE due to a change in composition of the remaining glassy phase was close to the CTE of the YSZ additive. A related glass composite sealing system based on the addition of Al_2O_3 to BCABS glass has been reported, where crystallization kinetics and long-term thermal stability of the glass were investigated (Huang *et al.*, 2018). In other work, based on a Ba free composition, the incorporation of aluminum nitride (AlN) into borosilicate glasses and glass-ceramics was investigated with the aim of improving the sealing performance by forming borosilicate GCMCs (Li *et al.*, 2019b). The experiments performed

Fig. 2 Schematic presentation of a SOFC stack and a SEM cross-sectional microstructural image of the sealant in one of the investigated SOFC designs. Energy* 44 (33), 18308–18318, with permission from Elsevier Ltd. (TBC).

indicated that AlN doping reduced the electrical conductivity and the composites exhibited a significant enhancement of thermal and chemical compatibility with the Y_2O_3 - ZrO_2 electrolyte.

Biomaterials

Biomaterials include those materials able to directly interact with biological systems, replace and/or repair tissues and organs or restore the function of tissues in the body (Ratner, 2019). Therefore, these materials must exhibit a range of optimized properties, i.e., chemical stability or controlled degradability, mechanical and biological properties, which depend on the functions they will have in contact with the biological system (Ratner, 2019). In this section, we take into consideration bioactive glass and glass-ceramic composites reported in literature and used in medical applications such as bone substitution and repair, dental restoration, implants, tissue engineering and drug delivery devices (Crovace *et al.*, 2016). Glass-ceramics for dental application can be divided into the following two main groups: restorative and bioactive (Montazerian and Zanotto, 2017). Most restorative dental glass-ceramics are used in the restoration and reconstruction of teeth because they are inert and biocompatible. Bioactive dental glass-ceramics, on the other hand, play an important role in the stimulation of biological reactions at the material/tissue interface. Even though bioactive glasses are characterized by outstanding bioactive properties, they suffer from low mechanical strength and low fracture toughness (Hench and Jones, 2015). In fact the bending strength of dense bioactive glass is close to 70 MPa and the fracture toughness K_{IC} shows values of $\sim 0.5 \text{ MPa m}^{1/2}$, which limit the fields of applications (Hench and Jones, 2015). To solve this issue and improve the mechanical performance of bioactive glasses and GCs, many studies have been conducted aiming at the development of bioactive GMCs and GCMCs.

Glass-ceramics for dental restoration need to satisfy distinctive requirements such as translucency and color, specific high strength, wear, toughness and Young's modulus together with a good compatibility with the oral cavity similar to those of natural teeth (Rampf and Höland, 2019). Recent developments have considered the addition of particles, fibers and also the use of advanced technologies, such as in sintering, molding and machining applying CAD/CAM or 3D printing, to manufacture novel dental materials (Galante *et al.*, 2019). The main glass-ceramic materials used in dental restoration applications are: (1) leucite-, (2) mica- (SiO_2 - Al_2O_3 - MgO - K_2O - B_2O_3 -F) based and (3) lithium disilicate-based glass-ceramics. Many works in the literature have shown that incorporation of ZrO_2 particles into matrices of lithium disilicate (Huang *et al.*, 2014), silicate (Chen *et al.*, 2020; Elsaka and Elnaghy, 2016) and mica (Gali, 2019; Yang *et al.*, 2011; Montazerian *et al.*, 2008a) is an effective method to enhance the mechanical properties of glass-ceramic matrices. In fact, ZrO_2 can induce transformation toughening and has crack deflection toughening effects. This is because the phase transition in ZrO_2 grains causes an expansion in the volume of the ZrO_2 particles leading to compressive stresses or to the formation of microcracks around the main crack. This behavior leads to a consumption of the energy of the main crack and as a consequence to an increase of the fracture resistance of the glass-ceramic (Apel *et al.*, 2007; Yang *et al.*, 2011). Another study (Huang *et al.*, 2014) has shown that the amount of ZrO_2 plays an important role in the improvement of the strengthening effect in disilicate GCMCs. However when the content of ZrO_2 particles was above 15–20 wt% manufacturing problems appeared (Chen *et al.*, 2020). In another study, Elsaka *et al.* (Elsaka and Elnaghy, 2016) developed a ZrO_2 -reinforced lithium silicate glass-ceramic with improved value of fracture toughness and flexural strength with respect to those of the lithium silicate GC matrix. Leucite glass-ceramics are usually fabricated by the controlled crystallization of leucite in the same ternary phase system (SiO_2 - Al_2O_3 - K_2O) as the conventional feldspathic porcelains, but with a higher amount of K_2O ($\sim 12 \text{ wt\%}$).

Chatzistavrou *et al.* (2012) have reported the fabrication of bioactive GCMCs for dental applications via a sol-gel process. The fabrication involved mixing commercial high fusing leucite based feldspathic porcelain powder (particle size 20–63 μm) with sol-gel derived bioactive glass. The sol-gel process was applied to obtain homogenous porous-free coatings on the surface of dental ceramic substrates creating bioactive coatings with strong bonding at the interface. In the work of Kumar *et al.* (2016) the effect of Al_2O_3 on leucite based bioactive glass ceramic composite for dental veneering was investigated. Composites containing alumina reinforcement exhibited higher flexural strength than that of pure leucite GCs.

Some bioactive materials, such as Bioglass® 45S5 (BG), can bond to bone and soft tissues (Syed *et al.*, 2019). In addition, bioactive glasses are characterized by a high biocompatibility, outstanding bioactive behavior and, in some compositions, antibacterial properties (Syed *et al.*, 2019). The drawback of BGs is their poor mechanical properties, which worsen in the case of porous BGs, used for example in applications as bone tissue engineering scaffolds. Indeed many studies have been performed to improve the mechanical characteristics of BG-based scaffolds tailoring crystallization and altering the composition of classical BGs with the inclusion of second phases in the form of ceramic or metallic particles and fibers, as well as graphene, carbon nanotubes and apatite crystals (Rizwan *et al.*, 2017). These composites may have a wide range of potential applications for hard (bones and teeth) and soft tissue engineering (Rizwan *et al.*, 2017). In particular, to utilize the outstanding bone-bonding ability of BGs, composites with biocompatible metals, such as stainless steel (SS) 316-L fibers and magnesium alloys, have been prepared (Huan *et al.*, 2010; Ducheyen and Hench, 1982; Schepers *et al.*, 1989). The Mg alloy ZK-30 has been used to reinforce BG matrices to improve its bone-bonding ability and to increase the resistance against corrosion in physiological fluids (Huan *et al.*, 2010, 2011). Moreover, Jurczyk *et al.* (2011) reported the fabrication of Titanium–10 wt% 45S5 BG nanocomposites for biomedical applications. Synthetic hydroxyapatite (HA) or tricalcium phosphate (β -TCP)-BG composites have been also extensively proposed (Rizwan *et al.*, 2017). Demirkiran *et al.* (2011) studied the bioactivity and biomineralization performance of HA composites with additions of up to 25 wt% of BG. BG was shown to act as sintering aid, promoting the occurrence of a minor β -TCP phase in the HA matrix. A significant increase in the mechanical properties was also observed by increasing the BG content up to 25 wt%.

Bellucci *et al.* (2013) developed a new hydroxyapatite-based BG biocomposite for bone replacement. The resulting composites could be sintered at a relatively low temperature (800°C) due to the use of a new glass with a reduced tendency to crystallize compared to 45S5 BG. The manufacturing of 3D-printed glass/HAp composites has been also reported (Winkel *et al.*, 2012). Furthermore, Schickle *et al.* (2011) fabricated a BG composite with 40 wt% β -TCP and studied its biocompatibility. The combination of bioinert and bioactive materials to produce bioceramic composites has been also investigated for bone tissue engineering applications. Si_3N_4 is a bioinert ceramic that can be combined with BGs to improve biocompatibility. BG acts also as sintering aid in the sintering process of Si_3N_4 . Frajkorová *et al.* (2015) developed and characterized porous composites based on Si_3N_4 containing sol-gel derived BGs. Amaral *et al.* (2002, 2007) fabricated and characterized Si_3N_4 -BG composites (30 wt% BG) for applications in hip and knee joint implants, using hot pressing between 1300°C and 1500°C. Furthermore, graphene and carbon nanotubes (CNTs) have been employed to develop composites in combination with BGs aiming at improving their mechanical properties and bioactivity (Xie and Cerruti, 2015). Porwal *et al.* (2014) fabricated BG matrix composites containing 0–5 vol% graphene nanoplatelets (GNP) by using spark plasma sintering (SPS) at 600°C and 70 MPa for 2 min. The BG-graphene composite showed high bioactivity, improved electrical conductivity and high density (99%). Similar composites were reported by Li *et al.* (2017). In addition, Porwal *et al.* fabricated a 45S5 BG-MWCNT (multi-walled carbon nanotubes) composites (Porwal *et al.*, 2015). SPS was used as it enabled fast sintering of the matrix to minimize damage of the MWCNT structure. The BG-MWCNT composites exhibited high electrical conductivity, about 8 orders of magnitude higher than that of the matrix, with the addition of 6.35 wt% of MWCNTs. The steps followed for preparation of the powder mixture to fabricate BG-MWCNT composites are illustrated in Fig. 3.

Finally, it must be mentioned that preceramic polymers, especially in the form of silicone resins, have a distinctive advantage to use advanced shaping technologies, including additive manufacturing, for the synthesis of bioceramics. Calcite (CaCO_3), a widely-recognized bioactive material, may be easily included in silicone-based pastes used in direct ink writing of reticulated scaffolds. The thermo-oxidative decomposition of the silicone polymer to obtain a ceramic matrix, if performed below 650°C, does not lead to the degradation of calcite particles (Fiocco *et al.*, 2017). Analogous thermal treatments, for example conducted in inert (N_2) atmosphere, bring additional opportunities, with the transformation of the silicone into amorphous silica embedding nano-dispersed pyrolytic carbon (Elsayed *et al.*, 2018). Such carbon phase may be found even by processing at higher temperatures, at which an extensive silicone-filler interaction occurs, leading to the formation of Ca silicate and Ca-Mg silicate crystals (Fiocco *et al.*, 2018). Carbon inclusions are very promising in making the composites sensitive to photothermal effects (heating induced by absorption of infrared radiation), that could be exploited in bone tissue engineering applications for the sterilization of scaffolds before implantation or for thermal ablation therapy of bone tumors (Fu *et al.*, 2020; Zhu *et al.*, 2020).

Med.* 26 (6), 199, with permission of Springer Science + Business Media New York.

Electronic Substrates

GMCs and GCMCs are considered important materials for electronic applications, for example to make microelectronic packaging substrates (Zawrah *et al.*, 2017). They must have low dielectric constant and low CTE ($\leq 8\text{--}12 \times 10^{-6} \text{ K}^{-1}$) (Susan *et al.*, 1992). In addition such substrates are designed to be useful for integrated circuits (IC) because they can be densified at relatively low temperatures. The use of glass or glass-ceramic matrices lowers the sintering temperature and allows the co-firing with low resistance conductors such as gold and copper (Zawrah *et al.*, 2017). In the work of Zawrah *et al.* (2017), Li-Na-K containing feldspar was added to borosilicate glass to fabricate GMCs for electronic substrate applications. The results revealed that the combination of Li-Na-K feldspar and borosilicate glass led to composites exhibiting the required electrical properties (dielectric constant ~ 5) and thermal expansion ($\leq 8\text{--}12 \times 10^{-6} \text{ K}^{-1}$) suitable for electronic applications. Morsi *et al.* (2019) fabricated composite materials based on Zn-titanate and borosilicate glass with different compositions. Willemite, rutile and Zn_2TiO_4 were the main crystalline phases in the composite. Electronic conduction was dominant over ionic transfer, suggesting the potential use of these composites as semiconductor materials in electronic devices.

The low-temperature co-fired ceramic (LTCC) technology to prepare multilayer GC substrates has been shown to be the most promising approach for successful microelectronics packaging (Waser, 1992). In LTCC a flexible raw material (green tape) is used as the base. This unsintered film consists of a mixture of glass, ceramic particles and organic solvents. Many tapes are based on borosilicate glass-ceramic composites containing up to 55 vol% of dispersed ceramic particles. The possibility of co-firing several layers simultaneously, consisting of dielectric ceramics with an internal metallic electrode with matched physical and chemical properties between the layers, has the advantage of reducing fabrication variability and costs (Kim and Koh, 2008). Substrate materials with sintering temperature $< 900^\circ\text{C}$ have been developed using rare earth derived borate glass ($\text{La}_2\text{O}_3\text{--B}_2\text{O}_3\text{--TiO}_2$) and $\text{BaO--Nd}_2\text{O}_3\text{--TiO}_2$ (BNT) ceramic additions (Jung *et al.*, 2005). Also, the fabrication of $\text{CaO--B}_2\text{O}_3\text{--SiO}_2$ glass/ CaSiO_3 (CBS/CS) composites via sol-gel process has been introduced (Wang *et al.*, 2011). The variation of density, microstructure and dielectric properties was investigated. It was found that the CS ceramic phase acted as functional filler and it had also an effect on the densification and dielectric properties of the composites. The dielectric properties of the CBS/CS composites obtained with 10% CS (sintered at 850°C) were $\epsilon_r < 5$ and $\tan\delta = 6.4 \times 10^{-4}$ at 1 MHz. Related composites have been developed based on forsterite- $\text{Li}_2\text{O--B}_2\text{O}_3\text{--SiO}_2$ (LBS) for substrates in electronic packaging applications (Sasikala *et al.*, 2008). Forsterite shows low electrical conductivity and dielectric constant, high chemical stability and refractoriness as well as excellent insulation properties, which suggest its use as substrate material in microelectronics. However, forsterite presents a relatively high sintering temperature ($\sim 1500^\circ\text{C}$) which makes it not usable for fabrication of multilayer components. The influence of glass addition on the densification, sintering temperature and dielectric properties of forsterite ceramics has been investigated (Sasikala *et al.*, 2008). Fig. 4(a)

Fig. 4 SEM images of (a) pure Mg_2SiO_4 , (b) $\text{Mg}_2\text{SiO}_4 + 1 \text{ wt\% LBS}$, (c) $\text{Mg}_2\text{SiO}_4 + 5 \text{ wt\% LBS}$, (d) $\text{Mg}_2\text{SiO}_4 + 15 \text{ wt\% LBS}$. Reproduced from Sasikala, T.S., Suma, M.N., Mohanan, P., Pavithran, C., Sebastian, M.T., 2008. Forsterite-based ceramic-glass composites for substrate applications in microwave and millimeter wave communications. *J. Alloy. Compd.* 461, 555–559, with permission of Elsevier B.V.

shows a SEM image of pure forsterite fired at 1500°C, showing a poorly densified microstructure. In Fig. 4(b)-(d), SEM micrographs of forsterite containing 1, 5 and 15 wt% of LBS glass, respectively, are shown. The micrographs indicate a significant degree of densification of the composite samples which is likely due to the beneficial effect of the glass. The microstructures shown in these micrographs suggest a good wettability of the glassy phase leading to a uniform and homogeneous distribution of the crystalline phases during the sintering process. The addition of 15 wt% LBS glass was found to reduce the sintering temperature from 1500°C to about 950°C without markedly affecting the dielectric properties. In addition, the synthesis and characterization of CaO-B₂O₃-SiO₂ (CBS) glass/ceramic composites for LTCC application has been investigated (Chen *et al.*, 2009). In this study, CBS glass/cordierite (Mg₂Al₄Si₅O₁₈) composites were prepared using standard ceramic process. The CTE decreased with the increase in cordierite content, achieving values in the range of $2.2 \times 10^{-6}\text{K}^{-1}$ to $5.2 \times 10^{-6}\text{K}^{-1}$, while the dielectric constant was found to be in the range of 5.2–6.2. Eberstein *et al.* (2009) employed α -Al₂O₃ particles as rigid inclusions in aluminoborosilicate glass to prepare substrates for LTCC applications. The dissolution of alumina in the matrix, sintering kinetics, and crystallization behavior of those GMCs were studied (Müller *et al.*, 2009). Composites of 75 vol% alkali-free 38CaO-4.7Al₂O₃-7.3B₂O₃-50SiO₂ glass (mol %) and 25 vol% commercial alumina powder were prepared. No substantial alumina dissolution in the matrix was found during densification of the composite. The influence of AlN addition on thermal and mechanical properties of cordierite-based glass/ceramic composites has been also investigated (Chen and Liu, 2007). The thermal conductivity of AlN/cordierite-based GCMCs was significantly improved by incorporation of AlN particles. The composite containing 50 vol% AlN exhibited a relatively high thermal conductivity of $6.5 \text{ W m}^{-1}\text{K}^{-1}$. In addition, the mechanical properties of the composites were also improved by incorporation of AlN particles. For example, by addition of 40 vol% AlN, the flexural strength and fracture toughness increased by 81% and 139% respectively, compared to the cordierite-based glass matrix.

The preparation of LZS (Li₂O-ZrO₂-SiO₂) glass-ceramic composites containing Al₂O₃ has been also reported (Arcaro *et al.*, 2017). LZS glass-ceramics exhibit relatively high mechanical strength and hardness as well as high abrasion and wear resistance. However, a limitation for their use as substrates in microelectronic packaging (LTCC technology) is their relatively high CTE ($8.8\text{--}10 \times 10^{-6}\text{K}^{-1}$). Incorporation of alumina nanoparticles to LZS GC matrices was investigated, which led to a significant reduction of the CTE.

Structural Applications

As mentioned above, LAS GCs have been investigated extensively for thermomechanical applications due to their low CTE over a wide temperature range (Xia *et al.*, 2015). Applications of LAS GCs range from microelectronic substrates to precision optics, specifically in components where dimensional stability and precision are required; the typical features provided by low CTE (Xia *et al.*, 2015). On the other hand, LAS GCs exhibit low strength and fracture toughness, typical of brittle GCs, which represents an important disadvantage of LAS GCs for structural applications. To improve the mechanical properties of LAS GCs, carbon fiber reinforced LAS GCMCs with B doping have been fabricated (Xia *et al.*, 2013, 2015). The main goals behind the development of such B-doped GCMCs were the increase of the fracture toughness of the LAS glass-ceramic, the reduction of the viscosity of the LAS matrix and the formation of a graphite layer on the surface of carbon fibers. A remarkable improvement in the mechanical properties was obtained in comparison with the pure LAS matrix composite achieving flexural strength and fracture toughness values of 640 MPa and $19.9 \text{ MPa m}^{1/2}$, respectively. Furthermore, boron doping led to an improvement of the oxidation resistance of the composites at temperatures in the range 600–1000°C.

A BAS glass-ceramic is another structural material that has been considered as suitable matrix for developing GCMCs for high temperature applications. This is based on the high melting temperature (1760°C) of BAS, and its good oxidation resistance and low CTE ($2.29 \times 10^{-6}\text{K}^{-1}$) (Ma *et al.*, 2009). However, BAS glass-ceramics have relatively low flexural strength and fracture toughness ($1.8 \text{ MPa m}^{1/2}$), which limits its use in many load-bearing applications (Ma *et al.*, 2009). Particulate (Ye *et al.*, 2005), whisker (Ye *et al.*, 2003a), platelet (Ye *et al.*, 2003b) and continuous fiber (Bansal, 2005) reinforcements have been investigated to obtain BAS GCMCs with improved mechanical behavior. For example, short silicon carbide and carbon fiber reinforced BAS GCMCs have been obtained by hot-pressing (Ma *et al.*, 2009). Typical microstructures of such composites are shown in Fig. 5, indicating that the fibers are homogeneously dispersed in the BAS matrix in both cases.

Dense BAS and Ba_{0.75}Sr_{0.25}Si₂Al₂O₈ (BSAS) GCMCs reinforced with short carbon fibers (C_{sf}) have been also fabricated by hot pressing (Ye *et al.*, 2008). The carbon fibers showed chemical compatibility with the GC matrices investigated, exhibiting the desired strengthening and toughening effects. By incorporating 30 vol% fibers, increases of 127% and 92% in flexural strength and fracture toughness were achieved compared to the unreinforced BAS GC matrix. The effects of the addition of BN (with doping contents of 10–50 wt%) on the microstructural evolution and mechanical properties of BAS-BN composites fabricated by hot-pressing have been also investigated (Li *et al.*, 2019a). Significant strengthening and toughening effects were confirmed by the incorporation of BN: the flexure strength increased in 123%. BAS-BN composites containing 30 wt% BN showed flexural strength and fracture toughness of $193.5 \pm 6.2 \text{ MPa}$ and $2.57 \pm 0.05 \text{ MPa m}^{1/2}$, respectively. In related research (Aggelis *et al.*, 2013), structural composites based on BMAS GCs reinforced with SiC-Tyranno fibers were prepared by hot-pressing at 1200°C. In this type of composite, a carbon-rich layer usually forms in-situ at the fibers' surface during hot-pressing due to the reaction of SiC with the oxides in the GC matrix. This carbonaceous layer is responsible for the toughening effect of the fibers as it provides a weak fiber/matrix interface leading to significant energy dissipation mechanisms during fracture. These include interfacial debonding, fiber sliding, fiber bridging, and pull-out.

Fig. 5 SEM micrographs of BAS GCMCs with (a) short carbon fiber and (b) short SiC fiber reinforcement. Reproduced from Ma, J., Ye, F., Liu, L., Zhang, H., 2009. Processing and mechanical properties of short fibers/Si₃N₄p reinforced BaO · Al₂O₃ · 2SiO₂ ceramic matrix composites. *Mater. Sci. Eng. A* 520, 158–161, with permission of Elsevier B.V.

A different family of GMCs and GCMCs has been developed more recently exploiting CNTs as the reinforcing phase. For example, MWNT/BAS GCMCs containing 10 vol% MWNTs were successfully fabricated by hot-pressing (Ye *et al.*, 2006) and achieved values of flexural strength and fracture toughness 192% and 143% higher than the matrix, respectively. MWNT pull-out and bridging were identified as the acting toughening mechanisms. In the work of Subhani *et al.* (2013), a comprehensive analysis of published data in the field of CNT-glass/glass-ceramic matrix composites has been published. Indeed numerous studies have reported CNT containing GMCs and GCMCs, including silica (Ning *et al.*, 2003; Xu *et al.*, 2009; Hongbing *et al.*, 2005; Zheng *et al.*, 2008), borosilicate (Thomas *et al.*, 2009), BAS (Ye *et al.*, 2006), aluminoborosilicate (Mukhopadhyay *et al.*, 2011), (Otieno *et al.*, 2010) and vanadium-doped silicate (Giovanardi *et al.*, 2010) matrices. It is found in general that addition of CNTs increases the fracture strength and toughness of the glass or GC matrices and leads to an increase of thermal and electrical conductivity. Even if the improvement in fracture toughness is not as marked as the one achieved by using fiber reinforcement, CNT containing composites show functional properties and cost-effective production, which are advantages that warrant more research in this field. Similarly, GCMCs produced by introducing α -SiC particles and densified by spark plasma sintering also show promising properties (Liu *et al.*, 2010).

Final Remarks

New applications for glass and glass-ceramic matrix composites have emerged and several publications describe the development of different composite systems and fabrication processes. The use of GCMCs in advanced applications like seals in solid oxide fuel cells and biomaterials has been increasingly successful. The period covered in this chapter has also seen an increase in research on novel reinforcement materials for the development of GMCs and GCMCs, in particular carbon nanotubes and graphene or graphene oxide. The literature reviewed has highlighted the efforts addressed to the development of advanced composites in terms of thermo-mechanical robustness and reliability in many different applications, exploiting the advantages of glass and glass-ceramic processing in comparison to polycrystalline ceramics, in particular lower processing temperatures. However a number of challenges remain for the future perspectives and further development of cost-effective and automated processing methods. It is evident that the field will benefit from continuous collaboration among materials scientists, engineers, designers and end-users to design and develop new fillers/reinforcements as well as alternative matrices. It can be anticipated that further efforts will involve dedicated research to improve the reliability of these composites taking into consideration the wide scope for new application fields and the possibility that composite technology offers to combine mechanical robustness and the added functionalities provided by the fillers.

This is a reprint of A.R. Bunsell, High Performance Fibers, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.02231-1.

Fiber Development

High performance synthetic fibers often resemble textile fibers in appearance and some are of the same chemical composition; however, they are produced so as to optimize their mechanical properties to achieve enhanced performance (Bunsell, 2009; Hearle, 2001; Chawla, 1998; Moncrieff, 1979).

Such fibers are used in structures for which their flexibility, lightness, and very high mechanical properties, compared to bulk materials, make them indispensable. These fibers have higher strengths and often higher elastic moduli than conventional textile fibers due to the manufacturing processes employed and also, in many cases, due to their molecular or atomic structures. In the case of some high performance fibers, their properties can attain almost the limits of what is physically possible so that very high moduli, even up to that of graphite, can be achieved. Some fibers have been developed to possess great thermal stability for uses at temperatures above the limits at which high performance metals can be used. Although stiff along their lengths fibers are flexible when bent because of their small diameters, which are usually of the order of 10 μm . They are used in applications including high performance tethering ropes, flexible architectural structures, reinforced elastomers, and fiber reinforced composites.

The commercial development of synthetic fibers began in the 1930s with the production of glass fibers in the USA. Glass and glass fibers have approximately the Young's modulus and density of aluminum. Although fibers made from regenerated cellulose, from wood, or other plants, were produced, first in France, toward the end of the nineteenth century and are known as rayon or viscous rayon the first truly synthetic polymeric fibers were produced in 1938. These were polyamide 6.6, developed in the USA and polyamide 6 fibers produced in Germany. These polyamide, or 'nylon' fibers, together with polyester fibers developed in Great Britain in the 1940s are the most important synthetic textile fibers produced. Although of low stiffness, they were the first of a family of organic fibers which have been developed with elastic moduli rivaling and even exceeding that of steel, but with only a fifth or less of the weight. These organic fibers find, however, many industrial applications as in tire reinforcement and anchor lines for off-shore oil platforms. Boron and silicon carbide fibers made by CVD onto a filament of tungsten or carbon were first produced in the early 1960s first in the USA and then in France and Russia. They have the density of glass but twice the Young's modulus of steel. Despite their remarkable properties boron fibers find very limited use because of their high cost. Silicon carbide fibers made by chemical vapor deposition are principally of interest for reinforcing titanium for jet engine applications. Both types of fibers have large diameters of 140 μm which greatly reduces their flexibility and this also limits their use.

Carbon fibers, with a density of a quarter that of steel, were first produced in Great Britain in the middle 1960s. They are made by the pyrolysis of polyacrylonitrile (PAN) precursor fibers and commonly have moduli up to one and half times the modulus of steel but can be up to three times stiffer. An alternative process developed in the 1970s in the USA uses the pitch residue from oil refining or the coking of coal to give fibers with moduli approaching that of graphite. Fine ceramic fibers, for structural applications, started to appear at the end of the 1970s and in the 1980s. One group of these fibers developed in Great Britain and in USA, is based on alumina whereas others developed in Japan are based on silicon carbide. These fibers have Young's moduli ranging from that of steel to twice this value with densities less than half that of steel.

Most fibers have diameters of the order of 10 μm , which can be compared to 70 μm which is the diameter of a human hair. Exceptions however are the boron and SiC fibers made by chemical vapor deposition (CVD) onto cores, which are twice as thick as hair. The fineness of fibers allows even the stiffest of materials to be made in a flexible form as bending stiffness is related to the fourth power of the diameter. However many high modulus fibers are completely elastic, at least at room temperature, and are therefore brittle in tension and in bending. They are most suited to be used as reinforcements in composite materials. The high performance polymer fibers are also used as reinforcements, such as in tires and other composites, but they are not brittle as they deform plastically in compression. They show great toughness which can be exploited in structures such as cables and structures which must resist impacts.

Organic Fibers

Polyamide (PA) or 'nylon' fibers were developed in 1938 by Du Pont in the USA and in Germany by I.G. Farben. These fibers are based upon amide groups ($-\text{C}(\text{O})\text{NH}-$) contained within a chain of carbon atoms making up a backbone of atoms linked by strong covalent bonds (Table 1). However the molecules are linear and can bend and rotate at each bond so that the molecules are not perfectly aligned parallel to the fiber axis, which results in a low Young's modulus. Around 1947 polyethylene terephthalate (PET) or 'polyester' fibers were produced in Great Britain and have become the most widely produced synthetic fibers. Table 1 shows that the polyester molecule contains an aromatic ring which stiffens it compared to the very flexible polyamide structure.

Table 1 Molecular composition of high performance organic fibers

Fiber type	Repeat unit in the macromolecule	Maximum elastic modulus (GPa)	Melting or decomposition temperature °C
Polyamide 6 (Nylon 6)	$\left[\text{NH}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{NH}-\text{CO}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CO} \right]_n$	4	230
Polyamide 6/6 (Nylon 6.6)	$\left[\text{NH}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CO} \right]_n$	5	260
Polyethylene terephthalate (Polyester)	$\left[\text{O}-\text{CO}-\text{C}_6\text{H}_4-\text{CO}-\text{O}-\text{CH}_2-\text{CH}_2 \right]_n$	18	260
Polyethylenene naphthalate (PEN)	$\left[\text{O}-\text{C}(=\text{O})-\text{C}_{10}\text{H}_6-\text{C}(=\text{O})-\text{O}-\text{CH}_2-\text{CH}_2 \right]_n$	35	275
Vectran	$\left[\text{O}-\text{C}_6\text{H}_4-\text{C}(=\text{O}) \right]_x \left[\text{O}-\text{C}_{10}\text{H}_6-\text{C}(=\text{O}) \right]_y$	80	330
Poly(<i>m</i> -phenylenediamine-isophthalamide) Nomex	$\left[\text{NH}-\text{C}_6\text{H}_3(\text{NH})-\text{CO} \right]_n$	17	400
Poly-paraphenylene/3,4-diphenylether ter- ephthalamide (Technora)	$\left(\text{HN}-\text{C}_6\text{H}_4-\text{NHOC}-\text{C}_6\text{H}_4-\text{CO} \right)_m \left(\text{HN}-\text{C}_6\text{H}_4-\text{O}-\text{C}_6\text{H}_3-\text{NHOC}-\text{C}_6\text{H}_4-\text{CO} \right)_n$	70	500
Poly(<i>p</i> -phenylene terephthalamide) (Kevlar)	$\left[\text{HN}-\text{C}_6\text{H}_4-\text{NH}-\text{CO}-\text{C}_6\text{H}_4-\text{CO} \right]_n$	135	550
Poly(<i>p</i> -phenylene benzobisoxazole) (PBO) (Zylon)	$\left[\text{C}_6\text{H}_4-\text{C}_2\text{N}_2\text{O}_2 \right]_n$	280	650
Poly{2,6-dimidazo [4,5-b:4'.5'-e] pyridinylene-1,4 (2,5-dihydroxy) phenylene} (PIPD) M5	$\left[\text{C}_8\text{H}_4\text{N}_4\text{O}_2 \right]_n$	330	650

Figure 1 Fracture morphologies: Left, a polyamide 66 fiber broken in tension. Right, a polyamide fiber broken in fatigue.

Both polyamide and polyester fibers melt at around 260 °C. Although both of these latter fibers melt at around the same temperature, it is significant that the polyester fiber, which contains the aromatic rings, shows much higher resistance to discoloration at raised temperatures than does the polyamide fiber. A fiber which is related to PET fibers is the polyethylenenaphthalate (PEN) fiber. [Table 1](#) shows that this latter fiber is based on a molecule which has two aromatic rings which further increases the rigidity of the fiber. The three fibers mentioned above are made by drawing from the melt through a spinneret. The drawing rate determines the final properties. An undrawn fiber will have a strain to failure of some hundreds of a percent and tensile loading will produce not only a very high strain to failure but deformation will involve striction of the filament. Striction is when the diameter of the filament is locally reduced under load and in this region the molecular structure becomes aligned parallel to the fiber axis and the loading direction. Further loading induces an increase in the striction until all the specimen is reduced in cross section and the molecular structure is largely oriented parallel to the fiber axis. Fibers for textile end-uses are drawn during production so as to produce filaments with enhanced molecular orientation, higher strengths, and longitudinal stiffness but with reduced strains to failure, generally of the order of 30%. Striction is not usually seen with this type of fiber. High performance versions of PA and PET fibers, which are destined for industrial applications, are more highly drawn with further reduced strains to failure in the region of 20% for the former and 15% for the latter. PEN fibers are only produced as high performance industrial fibers and have strains to failure of around 6%. The molecular morphology of these fibers consists of microfibrils, with transverse dimensions of around 5 nm, arranged more or less parallel to the fiber axis. Regions within the microfibrils are composed of well ordered arrangements of molecules which are folded as in a concertina. The rest of the structure is made up of less well ordered regions so that the overall molecular structure is semi-crystalline with a crystalline content generally of the order of 40%.

A typical tensile fracture morphology of one of the above thermoplastic fibers is shown in [Figure 1](#) (left). Images of fiber failure morphologies have been cataloged by [Hearle et al. \(2006\)](#). It can be seen that the fracture surface consists of two regions; an initial inclined region corresponding to initiation at the surface and slow crack propagation normal to the fiber axis. The crack opens because of plastic deformation ahead of the crack. Rapid failure finally occurs when the remaining part of the section can no longer support the applied stress. Under particular cyclic conditions the same fiber fails in fatigue and one half of the fatigue break is shown in [Figure 1](#) (Right). The crack has initiated at or near the surface but instead of running normal to the fiber axis it has been deviated to run at a slight angle to the fiber axis, penetrating into the fiber section so that the remaining section finally fails by the tensile process. A particularity of this type of failure is that the minimum load has to be lower than a threshold level so that raising the cyclic loading pattern can stop fatigue failure.

Higher melting points or decomposition temperatures and much higher Young's moduli have been achieved by including more aromatic rings in the molecular main chain and by aligning these very rigid molecules parallel to the fiber ([Table 1](#)). These types of polymers are made by the technology of liquid crystal spinning, as illustrated in [Figure 2](#). Overall, within the melt or solution, the molecular alignment is random however orientation is achieved not by drawing but through the shearing of the solution when the solution passes through the spinneret. Molecular alignment in these fibers occurs because of the very stiff molecules are aligned preferentially parallel to the fiber axis by the shear forces in the spinneret and held together by hydrogen or Van der Waals' bonds. The straighter the molecule the higher the modulus achieved. These liquid crystal polymers do not usually lend themselves to melt spinning and are usually spun from a solution although the Vectran fiber, produced since the 1970s by Hoechst-Celene, is melt spun.

Vectran is a liquid crystal polyester based fiber which, as can be seen from [Table 1](#), has a molecular structure which is not perfectly straight. It is produced by the acetylation polymerization of *p*-hydroxybenzoic acid and 6-hydroxy-2-naphthoic. The good alignment of its molecular structure gives higher rigidity than that found with other polyester fibers but the form of the molecule

Figure 2 Spinning from a liquid crystal solution.

determines its ultimate rigidity. The fiber is the only melt spun liquid crystal fiber which is available and finds uses in applications such as sail cloth because of its rigidity and resistance in bending.

The aramid family of fibers are made up of aromatic polyamides. Nomex was the first fiber of this family, produced in the 1960s by Du Pont. Nomex is a meta-aramid which accounts for an elastic modulus little different from high performance PET but higher temperature resistance. Nomex is widely used for clothing for potentially hazardous conditions where fire is a danger. It is also widely used in paper form as a honey-comb structure in the aeronautical industry. Para-aramids can possess remarkably high Young's moduli, more than 20 times that of conventional polyamide fibers and twice that of glass, as shown in [Table 2](#). This group of fibers, first introduced as the Kevlar fiber from Du Pont, has been available since 1972. These fibers are made from a mesophase or liquid crystal solution of poly (*p*-phenylene terephthalamide (PPTA)) dissolved in concentrated sulfuric acid. If the appropriate concentration is made the solution consists of locally organized PPTA molecules which align with one another. The structure of aramid fibers is very well ordered, however they are highly anisotropic which results in them being weak in all directions except parallel to the fiber axis. A PPTA fiber called kevlar 29, which is used as a reinforcement for specialty tires and also high performance cables has been shown to possess a longitudinal modulus of 80 GPa but a transverse modulus of only 3 GPa ([Wollrett-Blitz et al., 2014](#)). The authors of this chapter obtained their results by a comparison of longitudinal and transverse tests on single fibers ([Wollrett-Blitz et al., 2016](#)). As a consequence of this anisotropy failure of these fibers is nearly always highly fibrillar although local creasing of the fiber can cause a more restricted failure morphology.

In tension Kevlar fibers are five times as strong as steel in air for the same weight. The fibers show little tendency to deform plastically in tension but when they are bent the side in compression undergoes plastic deformation which allows them to accommodate the imposed strain. This results in the fiber being difficult to cut as well as giving great tenacity and resistance to impact loading. Their highly anisotropic behavior means that the fibers are not used in primary loading structures subjected to compressive forces. Aramid fibers, other than Kevlar, which are commercially available are the Twaron fiber developed by Akzo in Holland, now produced by Teijin Twaron, also in Holland and the Technora fiber from Teijin in Japan. Technora is derived from poly-paraphenylene/3,4'-diphenylether terephthalamide, which, as can be seen from [Table 1](#), is not a straight molecule and as a consequence the fiber has an intermediate modulus of around 65 GPa.

In 1998 the Toyobo Company began the commercial production of the Zylon fiber. Its chemical composition is Poly(*p*-phenylene benzobisoxazole (PBO)). The fiber has remarkable properties, in tension, as can be seen from [Table 2](#). It has a Young's modulus which is 40% higher than that of steel with the density of an engineering plastic. Its Young's modulus is twice that of kevlar, since unlike kevlar, the PBO molecule, shown in [Table 1](#), is completely straight thus making the most of the covalent bonds in its structure. PBO fibers however suffer from poor compressive strength as molecular interchain cohesion is assured by Van der Waals' bonds. As can be seen from [Figure 3](#), the fiber fibrillates on failure due to its inherent anisotropy.

Table 2 Comparison of organic fiber properties

Fiber	Diameter (μm)	Specific gravity	Young's modulus E (GPa)	Strength σ (GPa)	Strain to failure ϵ (%)	Specific modulus E/ρ (GPa/g cm^{-3})	Specific strength σ/ρ (GPa/g cm^{-3})
Polyamide 66	30	1.14	<5	1	20	4	0.9
Polyester	20	1.38	15	1	15	10	0.7
Pentex	28	1.4	35	1.1	6	25	0.8
Vectran	20	1.4	65	3.8	3.3	46	2
Nomex	15	1.4	17	0.7	20	12	0.5
Technora	12	1.39	70	3	4.4	50	2.2
Kevlar 49	12	1.45	135	3	4.5	93	2.1
Zylon	12	1.56	280	5.8	2.5	180	3.7
Polyethylene	38	0.96	117	3	3.5	120	3.1

**Figure 3** Detail of the splitting of a Zylon *p*-phenylene benzobisoxazole (PBO) fiber.

Magellan International in collaboration with Du Pont in the US has taken over the development of a fiber, created by the researchers at Akzo in Holland, which at present is called M5. The fiber is said to possess a Young's modulus of 330 GPa or even higher, but, above all, superior compressive properties, such as molecular interchain cohesion, are ensured by hydrogen bonds. The down side of this however may be an increased propensity to absorb water. This fiber has a slightly higher specific gravity of 1.7 compared to other very high modulus organic fibers. Compressive strength is said to be four times higher than that of the PBO fibers and nearly three times higher than kevlar fibers. However the M5 fiber is not yet in general production.

The production of aramid and similar organic fibers involves complex and expensive chemistry however the high performance properties of the fibers is a result of the molecules being aligned parallel to the fiber's axis. Simpler polymers could, if all their molecules were aligned parallel to one another, give materials with the characteristics of high performance materials. Such fibers can be made using a sol-gel in which polyethylene is dissolved in a solvent to make a very dilute solution which is then spun. Such fibers were first produced in Holland by DSM, under the name Dyneema, and then Allied (now Honeywell) in the USA under the name Spectra. The fibers consist of polyethylene molecules which are aligned parallel to the fiber axis with molecular interchain cohesion assured by Van der Waals' forces. They have properties in tension rivaling those of the aramid fibers with a lower specific

Table 3 Compositions (% wt), density, and mechanical properties of various glasses used in glass fiber production

Glass type	<i>E</i>	<i>S</i>	<i>C</i>	<i>D</i>
SiO ₂	54	65	65	74
Al ₂ O ₃	15	25	4	
CaO	18		14	0.2
MgO	4	10	3	0.2
B ₂ O ₃	8		5.5	23
F	0.3			
Fe ₂ O ₃	0.3			
TiO ₂				0.1
Na ₂ O			8	1.2
K ₂ O	0.4		0.5	1.3
Density	2.54	2.49	2.49	2.16
Strength (20 °C) GPa	3.5	4.65	2.8	2.45
Elastic modulus (20 °C) GPa	73.5	86.5	70	52.5
Failure strain (20 °C) %	4.5	5.3	4.0	4.5

gravity (0.97). However their properties in compression are poor. These fibers are limited in temperature to a maximum of 120 °C as they melt around 150 °C and suffer from creep.

Glass Fibers

In 1931 two American firms, which were later to fuse to make the Owens Corning Fiberglas Corporation, developed a commercial method of spinning glass filaments from the melt through spinnerets. The melting point of the most widely used glass is around 1200 °C and the spinnerets are made from platinum. The holes in the spinnerets have diameters of 1 or 2 mm and drawing the filaments produces fibers having diameters usually between 5 and 15 μm. The spinnerets usually contain several hundred holes so that a strand of glass fibers is produced. Several type of glass exist but all are based on silica (SiO₂) which is combined with other elements to create specialty glasses. The compositions and properties of the most common types of glass fibers are shown in Table 3. The most widely used glass for fiber reinforced composites is E-glass. S-glass, which contains a greater amount of alumina, is used to make glass fibers with superior mechanical properties whereas type C has a much reduced alumina content and resists an acid environment. Type D, which has no alumina, but a high content of boron oxide is used for its dielectric properties.

The strength of glass fibers is usually much higher than that of bulk glass as they contain many fewer weakening flaws. However to prevent damage by abrasion they are coated with a protective size which also holds the strand together, acts as a bonding agent with resins and sometimes as an antistatic agent. The structure of glass fibers is amorphous with ionic bonds linking the atomic structure. There appears to be no appreciable residual stresses within the fiber and the structure is isotropic, which means that the Young modulus of glass in fiber form is the same as in bulk form. Glass fibers are cheaper than most other relatively high modulus fibers and do not require very specialized machines or techniques to handle them. Their elastic modulus is however low compared to many other fibers and the specific gravity of glass is relatively high. Glass fibers are most commonly used to reinforce resins which limits their use to less than 300 °C (usually less than 120 °C). Above this range densification of the glass occurs and the fibers become increasingly susceptible to slow crack growth from surface defects. Strength increases with decreasing temperature.

Deposited Fibers

Boron, the fifth element in the Periodic table, is the lightest element with which it is practical to make fibers and they were first produced in the USA at the beginning of the 1960s. Boron fibers are made by chemical vapor deposition in which a mixture of boron trichloride (BCl₃) and hydrogen (H₂) at around 1000 °C passes over a continuous tungsten filament heated by electric current. Boron is deposited on the tungsten filament which has a diameter of 12 μm.

The fibers have Young's moduli exceeding 400 GPa as shown in Table 4 and very high strength both in tension and in compression. This latter quality is enhanced by their large diameter of 140 μm. A cross section of a boron fiber reveals its tungsten core and boron mantle. Boron fibers have proved to be a good reinforcement for light metal alloys particularly when the fiber was protected by a coating of SiC or B₄C however their high cost of production has limited wide use of this type of fiber.

Silicon carbide fibers are also produced by CVD using various chlorosilanes such as CH₃ Si Cl₃ which gives 3HCl and SiC which is deposited onto a tungsten or carbon core. They are of primary interest for the reinforcement of titanium and intermetallic matrices. Fibers with diameters between 100 and 140 μm, are made. The fibers, until recently produced by Textron and now produced by Specialty Materials Inc., are known as SCS-*n*, where *n* is the number of microns of surface coating added onto the diameter to protect it during composite manufacture. SiC fibers have a Young's modulus greater than 400 GPa, as

Table 4 Properties of ceramic fibers produced by chemical vapor deposition

Fiber type	Manufacturer	Trade mark	Composition	Diameter (μm)	Density (g cm^{-3})	Strength (GPa)	Strain to failure (%)	Young's modulus (GPa)
SiC	Specialty materials (formerlyTextron)	SCS-6	SiC on carbon	140	2.7–3.3	3.4–4.0	0.8–1	427
	DERA	Sigma	SiC on tungsten	100	3.4	3.4–4.1	0.8	400–410
B	Specialty materials (formerlyTextron)		Boron on tungsten	100–140	2.57	3–6	1	380–400

**Figure 4** Cross section of a SiC fiber made by chemical vapor deposition (CVD) showing the tungsten core.

shown in [Table 4](#) and can be used to around 1000 °C. [Figure 4](#) shows the cross section of a SiC fiber made by CVD showing the tungsten core.

Carbon Fibers

Carbon is the sixth lightest element and the carbon–carbon covalent bond is the strongest in nature. Many fibers can be converted into carbon fibers, the basic requirement being that the precursor fiber carbonizes rather than melts when heated ([Kaverov et al., 1995](#)). Carbon fibers developed in the USA in the 1950s and early 1960s used fibers regenerated from cellulose. This proved a slow process as the carbon yield from cellulose is only 24% and the atomic structure was poorly organized. Their mechanical properties were not high however such fibers have high thermal conduction properties and are still used in carbon–carbon heat shields and brake pads.

Most carbon fibers though are made by a process developed first in Great Britain and then in Japan in the late 1960s based on the conversion of a modified form of acrylic textile fiber. PAN has a carbon yield of 49% and the properties of carbon fibers made by this route depend on the temperature of pyrolysis. The PAN fibers, held in tension, are first heated to about 250 °C in air which cross links the structure and makes it infusible. Further heating in an inert atmosphere to above 1000 °C eliminates most of the elements other than carbon and around 1500 °C a fully carbon fiber is achieved. At this temperature the strength of carbon fibers reaches a maximum. Above this temperature the basic carbon structural units increase in size which results in a fall in strength whereas the Young's modulus increases continuously with increasing temperature up to around 3000 °C. The structure which results from the pyrolysis of PAN is highly anisotropic, with the basic structural units formed by the carbon atom groups aligned

parallel to the fiber axis. There is complete rotational disorder in the radial direction and the relatively poor stacking of the carbon atoms means that a graphite structure is never achieved. The structure contains pores which account for the density of the fibers being less than that of fully dense carbon. **Table 5** shows some typical properties of carbon fibers, however there exists a considerable range of properties for these fibers. **Figure 5** shows a early PAN based carbon fiber which reveals the general appearance of the precursor fiber. More recently produced carbon fibers are smoother in appearance which helps to increase strength by reducing stress raising irregularities in the surface.

Carbon fibers made from pitch based precursors were developed in the USA in the early 1970s and in Japan in the 1980s. The high carbon yield of pitch which approaches 90% makes it an attractive and cheap source for making carbon fiber precursors. Cost

Figure 5 An early polyacrylonitrile (PAN) based carbon fiber.

however is increased by the purification processes by which the pitch is converted into a mesophase or liquid crystal solution which is then spun giving precursor fibers with aligned microstructures. From this point the fabrication route is the same as that for the PAN based fibers. Unlike PAN based fibers, there is no peak in strength at 1500 °C. Pitch based precursors heated to around 2300 °C give fibers with Young's moduli as high as those obtained with PAN based fibers at 2900 °C and heating to these higher temperatures gives even greater stiffness of up to four and a half times that of steel. It is therefore more economical to produce high modulus carbon fibers from pitch than it is from PAN. The properties are due to a less disordered, more graphitic microstructure of the pitch based fibers which however leads to lower compressive strength and increased costs in producing high strength carbon fibers.

In the absence of oxygen carbon fibers are the ideal reinforcement and can be used to above 3000 °C. However the fibers suffer from oxidation from around 400 °C so that they can be used for short exposure times, such in carbon-carbon composite rocket nozzles or heat shields for atmospheric re-entry vehicles, but not for long term applications above this temperature.

Oxide Fibers

Ceramic fibers can be divided into oxide and non-oxide fibers (Bunsell and Berger, 1999). The oxide of aluminum, alumina, is a hard brittle material with excellent refractory properties up to 1600 °C. The atomic structure of this material is assured by a mixture of covalent and ionic bonds. Fibers for structural applications based on forms of alumina were developed first in the UK and in the USA in the 1970s. Alumina exists in a range of phases of which the most stable and crystalline form, to which every other phase is converted around 1200 °C, is alpha alumina which has a Young's modulus of around 400 GPa. Several manufacturers have produced continuous α -alumina fibers as can be seen from Table 6. These fibers are made from slurries consisting of alpha-alumina particles, in an aqueous solution of aluminum salts which is spun and sintered. The control of grain growth and porosity in the production of alpha-alumina fibers is difficult so that the different manufacturing routes adopted have produced fibers with different Young's moduli. The Almax fiber, for example, contains considerable porosity which accounts for its lower modulus than that of Nextel 610.

The difficulties in producing pure alpha-alumina fibers can be overcome by the inclusion of silica in the structure and the development of intermediate alumina phases. The Young's moduli, around 200 GPa, of these fibers are lower compared to that of pure α -alumina and such fibers are produced at a lower cost. This, added to easier handling due to their lower stiffness, makes them attractive for thermal insulation applications, up to at least 1500 °C and as reinforcements for aluminum alloys in the temperature range of 300–350 °C. Alpha-alumina fibers and those of other phases containing silica resist oxidation at high temperature but the high diffusion rates of the elements in their structures above 1000 °C means that they creep and also lose strength around this temperature.

A series of fibers based on a mullite composition consisting of a ratio of 3 mol of alumina to two of silica has been developed by 3M. Mullite has a complex crystallographic structure which is highly resistant to creep at high temperatures. The Nextel 720 fiber from 3M consists of both α -alumina and mullite phases. The microstructure of the fiber is composed of mosaic grains of 0.5 μm with wavy contours, consisting of several slightly mutually misoriented grains and elongated grains. Its Young's modulus is 260 GPa. At high temperatures, above 1000 °C and up to 1500 °C the microstructure of the Nextel 720 fiber leads to a dramatic reduction in creep rate compared to pure alumina fibers but the fiber surface is particularly reactive to alkaline contamination above 1100 °C which leads to the development of grains as the surface and if this occurs, a fall of strength.

Table 6 Properties and compositions of alumina based fibers

Fiber type	Manufacturer	Trade mark	Composition (wt%)	Diameter (μm)	Density (g cm^{-3})	Strength (GPa)	Strain to failure (%)	Young's modulus (GPa)

SiC Based Fibers

Fibers, based on silicon carbide became available from Japanese producers in the early 1980s. They are made by the pyrolysis of organo-silicon precursor filaments based on polycarbosilane which consists of cycles of six atoms arranged in a similar manner to the diamond structure of β -SiC. The early Nicalon fibers made by Nippon Carbon and the Tyranno fibers from Ube Industries were made by first cross-linking the precursor fibers by heating in air which introduced oxygen into the structure. The Tyranno fibers already contained some oxygen as it was introduced with a small amount of titanium into the precursor to control spinning. The presence of the oxygen resulted in the SiC grains, about 2 nm in size, which were developed during pyrolysis, being surrounded by an amorphous Si-C-O phase and the fibers had Young's moduli of around 200 GPa. This intergranular phase caused the fibers to creep above 1000 °C and its degradation above 1200 °C limited their use. Cross-linking of the precursors by electron irradiation eliminated the need for introducing additional oxygen into the precursors. This process gave rise to the Hi-Nicalon fiber which had no significant oxygen rich amorphous phase, but considerable excess free carbon. The grain size of the Hi-Nicalon fiber is around 10 nm and its Young's modulus is in the range of 265–290 GPa. The fiber is more stable than its predecessors at temperatures above 1000 °C although grain growth occurs. Both Japanese manufacturers have produced a near stoichiometric SiC fiber by extending the above technology and heating the fibers to temperatures of around 1800 °C. The fibers differ in detail which leads to different ultimate properties, as can be seen in [Table 7](#), but all three have grain sizes greater than 50 nm and up to 200 nm. This leads to Young's moduli of up to 400 GPa. These fibers retain their properties in short term tests to around 1400 °C.

Concluding Remarks

A wide range of very different high performance fibers have been developed. Many have low densities making them attractive engineering materials, either embedded in a matrix to form a composite, or by themselves as ropes or other structures. These materials, which are still being improved, are destined to find a wide range of uses some of which would be impossible without the extraordinary properties of high performance fibers.

Chemical Processing

Chemical or sol-gel processing was first used to produce ceramic oxide fibers in the 1960s (Wainer *et al.*, 1965). A number of chemically derived alumina-silica fibers, notably Saffil (noncontinuous 95% Al_2O_3 -5% SiO_2 fibers) and Nextel™ 312 (continuous aluminum borosilicate fibers), were commercialized in the late 1970s (Stacy, 1988; Birchall *et al.*, 1985; Sowman, 1988). Most applications for these fibers are for thermal insulation, where load-bearing capability is not a major concern. More recently, fibers designed specifically for the reinforcement of composites have been produced, for example, DuPont's Fiber FP and Nextel™ 610 and 720 ceramic oxide fibers.

Oxide Fiber Precursor Chemistry

There are a number of alumina precursors available that are suitable for forming fibers. The aqueous chemistry of aluminum allows for the formation of viscous basic aluminum salt solutions that can be made into fibers by dry spinning. Polymeric aluminoxane precursors have also been used to produce alumina-based fibers. More recently, aluminoxanes that can be melt-spun into fibers have been produced. Details of both types of chemical precursor are given below.

The spinning solution or spin dope must be a high-viscosity ($10\text{--}100\text{ N s m}^{-2}$ (10 000–100 000 cP)) liquid, stable with respect to both crystallization and precipitation of insoluble salts and organic-containing complexes and to rapid increases in viscosity or gelation resulting from the progression of cross-linking of precursor species. Spin dopes prepared using exclusively colloidal sols (e.g., boehmite, AlOOH) are not suitable for forming continuous fibers because they are shear thinning. Colloidal SiO_2 is, however, commonly used as a component in oxide fiber spin dopes. Other SiO_2 precursors such as partially hydrolyzed alkoxides and polysiloxanes have also been used as a method of introducing SiO_2 into fiber compositions. Other inorganic modifiers to oxide fiber compositions can be readily added using soluble salts (e.g., nitrates). Long-chain organic polymers such as polyethylene oxide are commonly added to improve fiber-forming ability and green strength. Using organic polymers as spinning aids, spin dopes can also be prepared using slurries. Slurry-based fibers (e.g., Fiber FP) have high ceramic content relative to organics, so that shrinkage is reduced, leading to simple heat-treatment. Using slurries, a wide variety of compositions can be produced, limited only by the availability of submicrometer powders (French and Cass, 1998). For instance, BaTO_3 , PZT, YAG, and SiC fibers have been produced using a slurry technique. Sol-gel processes have also been used to prepare a variety of fiber compositions not based on alumina, including ZrO_2 , $\text{ZrO}_2\text{--SiO}_2$, TiO_2 , YAG, and Y_2O_3 .

Basic Aluminum Salts

Basic aluminum salts are salts with less than the stoichiometric 3 moles of anion per Al, and have the nominal formula $\text{AlX}_n(\text{OH})_{3-n}$, where X is a ligand such as Cl^- , NO_3^- , or CH_3COOH^- . Basic aluminum salts can be formed using a number of methods, including dissolution of aluminum metal in salt solutions, dissolution of aluminum hydroxides in acid, hydrolysis of alkoxides, and neutralization of acidic salt solutions. The polycationic complexes formed are stabilized against further cross-linking and hydrolysis by complexing ligands (Bertsch, 1989). Basic aluminum salts used for fibermaking contain 0.5–2.0 moles of anion ligand per mole of aluminum. If the amount of ligand is too low, gelation via cross-linking of polynuclear clusters will occur; high amounts of ligand cause difficulties during fiber heat treatment because excessively large amounts of fugitives must be removed during pyrolysis. Large ligands such as lactic acid or acetyl acetonate can be used to produce spinnable precursors but are not desirable, since ceramic yield on firing is lower than smaller ligands such as chlorine. Aluminum chlorohydrates ($\text{AlCl}_x(\text{OH})_y$) are used to prepare a number of commercial fibers, including Fiber FP and PRD-166, Almax™, and Alcen™. Rubilon™ and the Nextel™ series of fibers are produced using aluminum carboxylates.

Polymeric Aluminoxane

Aluminoxanes consist of an Al–O backbone polymer coordinated by chelating ligands such as carboxylates and aceto-acetonates (Glaubitt *et al.*, 1994; Yogo and Iwahara, 1992). Aluminoxanes are synthesized by the addition of the ligand to aluminum alkyls or alkoxides to partially chelate the aluminum, followed by the addition of 0.5–1 moles of water per mole of aluminum to polymerize the aluminoxane. Depending on the ligands used, these precursors can be either melt-spun or dry-spun. Melt-spun

Figure 1 Schematic of sol-gel fiber process.

fibers are cured (to make them infusible) by completing hydrolysis by exposure to humid atmospheres. Sumitomo Altex™ fibers are produced using this technique.

Figure 1 shows a schematic of the sol-gel fiber process. Spin dope is extruded through a spinneret to form small-diameter fibers. The fiber becomes rigid as solvent is evaporated. If the viscosity is too low, the extruded liquid spherodizes into droplets; too high, the fibers become brittle and are easily fractured. After spinning, the green fibers are conveyed into a furnace for heat treatment. Pyrolysis (the conversion of the chemical precursor into a ceramic) typically involves the loss of 50–80% of the initial weight of the green fiber. Volumetric shrinkage can be 80% or higher. Volatile components (including CO, CO₂, H₂O produced by oxidation, plus low molecular weight organics, depending on precursor chemistry) must diffuse out of the fiber during this stage. Thus, pyrolysis must be performed with care to gently decompose the green fiber to the oxide form without forming defects or flaws. Too-rapid evolution of gases can cause pinholes, bubble or void formation, or even bloating, trapping of carbon, phase separation, and cracking. The addition of colloidal or particulate slurries to fiber precursors increases ceramic yield, thereby reducing shrinkage and facilitating pyrolysis.

The goal of heat treatment is to develop a ceramic microstructure with both good strength and good high-temperature properties (i.e., resistance to thermal degradation via grain growth). To achieve high fiber strength at room temperature, a small grain size ($\leq 1.0 \mu\text{m}$) is required. The Griffith equation, $\sigma = K_{Ic} / \sqrt{\pi c}$, indicates that for Al₂O₃ ($K_{Ic} = 3$), a strength of 3 GPa can only be achieved if the flaw size c is $< 1.0 \mu\text{m}$. Thus, not only must defect concentration be kept low by careful fiber processing, but grain size should not exceed this limit. During fiber manufacture, extreme care must be taken in all process stages to prevent the formation of defects and flaws that reduce fiber strength.

Heat Treatment and Fiber Microstructure

Microstructures in alumina-based fibers must be viewed through an understanding of crystalline transformation sequences in alumina, and the effect of silica on microstructure and transformation kinetics. As shown in **Table 1**, all commercial oxide ceramic fibers are based on alumina with varying amounts of silica. The stable phases for alumina-silica fibers with $\leq 28\%$ Al₂O₃ at all temperatures are α -Al₂O₃ and mullite. However, a series of cubic alumina spinels commonly called transition aluminas form in the temperature range 800–1200 °C during heat treatment of alumina and alumina-silica precursors. The first phase to crystallize is either η -Al₂O₃ (cubic) or γ -Al₂O₃ (tetragonal), which form in the range 800–900 °C. In many systems, δ -Al₂O₃ and θ -Al₂O₃ are formed with additional heating in the range 1000–1150 °C. These polymorphs are similar to γ -Al₂O₃ but have a higher degree of ordering on the cation lattice. The transformation to α -Al₂O₃ (a hexagonal crystal structure) occurs above 1200 °C; Mullite (3Al₂O₃ · 2SiO₂) also may crystallize above 1280 °C.

For alumina and alumina-silica fibers, the crystallization of new phases such as mullite and α -Al₂O₃ often result in large grains, causing the fibers to become brittle and weak. A low volumetric nucleation density, which leads to large grain sizes, is typical of both alumina and mullite. For instance, crystallization of α -Al₂O₃ in high-alumina fibers causes the formation of large, porous, spherulitic grains several micrometers in size (McArdle and Messing, 1993). These large grains cause the fibers to become brittle and weak. To avoid this problem, most commercial fibers are stabilized as transition alumina by the addition of SiO₂. The addition of SiO₂ to alumina fibers increases the temperature of the α -Al₂O₃ transformation by as much as several hundred degrees centigrade. This allows the preservation of the submicrometer transition alumina microstructure (and therefore strength and flexibility) for extended periods above 1100 °C. At high silica contents, mullite may crystallize. B₂O₃ is added to some fibers as a grain growth inhibitor; B₂O₃ promotes the formation of a fine-grained mullite structure via 9Al₂O₃ · 2B₂O₃ intermediate phase (Richards *et al.*, 1991). High silica contents will lead to the formation of mullite above 1280 °C, which also can cause weakening of the fibers via grain growth.

Table 1 compares the density, strength, and elastic modulus of commercial ceramic oxide fibers. Commercial fibers can be divided into two classes: (1) those consisting of a mixture of transition alumina and amorphous silica; and (2) fibers containing crystalline α -Al₂O₃. Alumina-silica fibers have density between 2.7 and 3.2 and elastic modulus between 150 and 200 GPa.

Table 1 Composition and properties of commercially available oxide fibers^a

Fiber	Manufacturer	Composition Al_2O_3 - SiO_2	Density	Crystal phase	Tensile strength (GPa)	Elastic modulus (GPa)
Nextel™ 312	3M	62–24 (+ 14% B_2O_3)	2.7	$9Al_2O_3 \cdot 2B_2O_3 + am. SiO_2$	1.7	150

^aComposition data taken from vendor specifications, precursor composition taken from the patent literature.^bNo longer commercially available.

$\alpha-Al_2O_3$ fibers have much higher elastic modulus (380 GPa) as well as higher density (3.6 – 4.2 g cm^{-3}). Within each class, density and elastic modulus is inversely proportional to the alumina content: fibers with high alumina content have high elastic modulus and high density. The density and modulus of $\gamma-Al_2O_3$ is in the range 3.2 – 3.6 g cm^{-3} and 220 GPa respectively; the addition of SiO_2 at 2.2 g cm^{-3} and 70 GPa will reduce both. The addition of B_2O_3 will also reduce density and modulus. The effect of silica content on strength is less clear, since strength is related to flaw size and distribution as well as composition. Most fibers have tensile strength in the range of 1.7–2.1 GPa. An exception is Nextel 610, which has a strength of 3.0 GPa.

Fibers containing crystalline $\alpha-Al_2O_3$ have much higher chemical stability and elastic modulus than fibers containing transition aluminas. They are also not prone to shrinkage at high temperatures caused by crystallization and sintering, and can have higher creep resistance under load at high temperatures. For these reasons, they are used for the reinforcement of metal and ceramic composites; however, achieving fine grain size in $\alpha-Al_2O_3$ fibers is not straightforward. $\alpha-Al_2O_3$ has an intrinsically low volumetric nucleation density, which leads to large grain size and low strength. The addition of seeds or nucleation agents to promote high nucleation density during crystallization is essential if the fine grain sizes required for high strength ($0.5 \mu\text{m}$) are to be achieved. Seeding with submicrometer $\alpha-Al_2O_3$ particles (e.g., Fiber FP) or Fe_2O_3 -based nucleation agents (e.g., Nextel 610) have been used to produce fine-grained, high-density $\alpha-Al_2O_3$.

Ceramic oxide fibers have limited creep resistance at high temperatures compared with SiC fibers; however, progress in fiber processing during the 1990s has enabled the preparation of fibers with significantly improved high-temperature creep properties. Fibers with increased amounts of crystalline phases such as $\alpha-Al_2O_3$ and mullite, and lesser amounts of amorphous phases such as SiO_2 , have reduced deformation at high temperatures. For instance, Nextel 720 fiber, which consists of a mixture of $\alpha-Al_2O_3$ and mullite, has demonstrated considerably greater creep resistance above 1000°C than either alumina-silica or $\alpha-Al_2O_3$ fibers. This has been attributed to the presence of mullite, which is a more creep resistant phase than alumina, plus larger grain size. YAG fibers that exhibit even better creep resistance have been developed at several laboratories. Such YAG fibers have the potential for long-term composite reinforcement at 1200°C and above.

Ceramic Matrix Fiber Composites

Francis Rebillat, Laboratoire des Composites Thermostructuraux, University of Bordeaux, Pessac, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

Since the 1970s, the aerospace and aviation industry has constantly deepened its research to further improve the qualities of materials in order to extend their application to civil aeronautics. The development of nickel and cobalt-based superalloys are at their limits of use in terms of new environmental requirements, i.e., to obtain high efficiency (fuel economy, lower operating costs) and a reduction in pollution (noise level, emissions). One solution would consist of increasing the temperature of gases in the hot parts of the aircraft engines. The alloys currently used are limited to temperatures close to 1100°C and monolithic ceramics exhibit behavior too brittle for application. Only ceramic matrix composites (CMCs) are potentially able to fill the necessary requirements. Thus, their gradual replacements by composites, have accelerated over the past twenty years (Naslain, 2004). Current CMCs have a much lower densities than metallic materials and can have a much higher temperature capability. The need for high performance materials in industries as diverse as aeronautics, space, automotive, sport, etc., has led to the systematic development of composite materials (Krenkel, 1994; Krupka and Kienzle, 2000; Gadow and Speicher, 2001; Bouillon *et al.*, 2002; Bouillon *et al.*, 2004; Naslain, 2004; Cavalier *et al.*, 2006; Lacombe *et al.*, 2009). In order to be able to integrate this type of composites into the hot parts of the engines, it is necessary to adapt them to withstand the stresses imposed by this environment (high temperature 1400°C, oxidation, corrosion), while guaranteeing properties at least equal to those of superalloys used in terms of thermal conductivity, mechanical resistance, service life, etc. It is for this purpose that various research programs have been set up on new generation CMCs.

Structural composites generally consist of a fibrous reinforcement forming a reinforcement which constitutes the skeleton of the whole, and of a matrix which embeds the fibers. The different CMCs are designated in the form of two headings separated by a forward slash (e.g., C/C, C/SiC, SiC/SiC, oxide/oxide, etc.); the first designating the material of the fiber, the second that of the matrix (Chawla (2012)). These composites are generally said to be “thermostructural”, meaning that they can be used at high temperatures as structural materials. Thus, although monolithic ceramics are relatively hard and brittle, CMCs have the advantage of having non-brittle behavior. Their fields of application are currently mainly aeronautics, space and nuclear. Thus, they are subjected to temperatures ranging from 400°C to more than 2000°C in oxidizing atmospheres (air, reactor combustion gas, etc.) (Christin, 2002; Naslain, 2004; Rosso, 2006; Tang *et al.*, 2007; Padture, 2016).

Initially, this chapter gives a definition of composite materials and focuses on the general behavior of CMCs at room temperature, to show the interest in their development. Then, the general fabrication methods involved in introducing the ceramic matrix into the fibrous reinforcement is explained, in order to provide all the knowledge needed to choose a process and analyze recent developments in manufacturing.

Definition

A so-called composite material results from the association of at least two immiscible materials whose properties complement each other. Its architecture is tailored to achieve on a macroscopic scale, in preferred orientations, an original range of properties that its singular constituents don't possess.

The role of the fibrous reinforcement is to be a strengthening agent, essentially playing a mechanical improvement role. It brings rigidity and mechanical strength and can have preferred orientation. The fibers carry most of the applied load until the composite breaks, so that the breaking of fibers leads to the final failure of composite materials. The fiber constituent has to be protected against any kind of environmental degradation during application to prevent premature failure of composites.

Preforms, formed by the fibers, are densified by a ceramic matrix. The matrix has three main functions: (1) to keep the reinforcement in shape by ensuring the continuity of the material, (2) to ensure the transfer of loads applied to the composite to the fibers and (3) to protect the fibers and the interphase against degradation from the outside environment. In order to limit the residual stresses created during thermal cycling, the matrix must have a thermal expansion coefficient close to that of the reinforcement. The ceramic matrix can consist of a single homogeneous phase or it can include different phases in order to give it specific properties. Thus, there are so-called self-healing matrices which include compounds which, on contact with an oxidizing atmosphere, form glasses which seal the crack networks (Rebillat, 2014). Efficient reinforcement actions by the fibers depend on the interfacial bond strength between the fibers and the matrix in the composite.

Fibrous Reinforcement

Fibers must have a high tensile strength and elastic modulus, combined with good fatigue resistance. They must be thermo-chemically and mechanically compatible with all other constituents so as not to generate parasitic reactions and create networks of cracks by relaxation of high thermal residual stresses. Depending on the type of use, they must also exhibit good resistance to

Fig. 1 Various weavings for fibrous reinforcements in composite materials.

oxidation, creep and have low or high thermal conductivity. The fibers can be woven, braided or assembled in the form of semi-finished products (felts, unidirectional sheets, etc.), which constitute a preform of the final part. The fibers used in CMCs typically belong to a family of inorganic mineral fibers (Naslain, 2004; Rosso, 2006). Three types of fibers are generally used: carbon fibers, oxide fibers or carbide fibers (Lee, 1993; Bunsell, 2001).

The choice of fiber reinforcement directions is made with regard to the main loading directions (see Fig. 1). Differences between various weavings, in the way the fibers are laid out, give different strengths and ease of manufacture (Ko, 1989; Ko and Du, 1997). The degree of anisotropy decreases with the number of reinforcement directions. Delaminations between the layers of fabrics are avoided by adapting means of weaving to form three-dimensional weaves (Lee, 1993).

Mechanical Behavior

Properties of Constituents

Ceramic constituents are preferred for their refractoriness and thermal stability, chemical inertness and their low density. They are not considered to be mechanically reliable because of their brittle behavior and sensitivity to impacts. By making ceramic matrix composites, the goal is to introduce a different and more tortuous mode of crack propagation. Despite this while CMCs are composed of brittle constituents, they are assembled so as to form a non-brittle composite capable of being toughened by strain energy absorption, in particular due to weakening of the bond between fiber and matrix (Naslain, 1985, 2004; Bansal, 2005; Chawla, 2012). Because of this additional strain energy absorption mechanism, composites display non-linear elastic behavior and greater resistance to failure, as described below. CMCs are said “reverse”, compared to organic matrix composites, due to a failure deformation of the matrix lower than that of fibers.

Origin of the Non-Linear Behavior of a CMC

Given the high rigidity and low elongation to failure of ceramic matrices, the mechanical properties of a composite are closely related to the nature of the fiber/matrix bond which has chemical origin (interdiffusion and chemical reaction) and/or mechanical origin (thermomechanical shrinking and friction). When the strain in the composite reaches the strain at failure of the matrix, there is some matrix microcracking (Evans and Zok, 1994; Aveston *et al.*, 1971) and a greater load transfer from the matrix to the fibers. The fiber/matrix interface then plays a fundamental role in controlling resistance to failure. Indeed, the threshold interfacial shear stress (between the fiber and the matrix) must not be too strong in order to avoid brittle fracture (behavior close to that of the monolithic matrix) but sufficient to ensure load transfer from the matrix to the fibers (Guillaumat, 1994; Peres, 1988; Evans and Zok, 1994) (see Fig. 2). This is why the presence of a suitable interphase between fiber and matrix was investigated in depth (Aveston *et al.*, 1971; Naslain, 1998). It has long been established that the presence of an interphase of pyrocarbon brings better mechanical properties to a composite thanks to a adapted fiber/matrix bond, playing its role of crack deflector parallel to the fibers (Naslain, 1995) (see Fig. 2(b)).

Too weak a connection does not allow a sufficient load transfer from the matrix to the fibers, whereas too strong a bond leads to brittle rupture (rupture). A suitable bond allows crack deflection along the fibers from mode I loading, perpendicular to fibers, to mode II loading, parallel to fibers (see Fig. 2). This dissipates the energy of crack propagation by the creation of new fiber/matrix surfaces and friction (Guillaumat, 1994; Peres, 1988; Evans and Zok, 1994). The cracks then propagate within the matrix and the fiber bridging process (Marshall *et al.*, 1985). This makes it possible to limit the opening of cracks due to the loading thanks to the closing force exerted by the fibers.

Fig. 2 Damage in a CMC in function of the fiber/matrix bond strength: (a) strong bond and (b) weak bond.

Definition of an Interphase

An interphase is a thin layer that coats the fibers and provides the correct level of bonding between fiber and matrix. Its role is essential and the quality of the mechanical properties of the final composite are very closely linked to it (Kerans and Parthasarathy, 1991; Evans *et al.*, 1991; Rouby and Reynaud, 1993; Evans and Zok, 1994). It is thanks to the interphase in particular that a composite made up of brittle components can exhibit damage limiting behavior. In summary, it performs several essential functions:

- The load transfer between fiber and matrix takes place via the interphase. (Naslain, 1995).
- The interphase acts as a mechanical “fuse”, i.e., it limits the propagation of cracks by deflecting them from mode I to mode II loading, parallel to the fibers.
- The deviation of the crack can be localized within the interphase (cohesive failure) or at the I/F or I/M interface (adhesive failure) (Lamon, 2005).
- The interphase must attenuate local residual stresses of thermal origin that appear during processing at high temperature, linked to the difference in expansion coefficients between fiber and matrix.
- It also has a role in protecting fibers against oxidation.

The interphase must also have good chemical compatibility with the fibers and the matrix. Pyrocarbon is an interphase material that effectively fulfills the mechanical roles described. Its structure in layers parallel to the fiber direction allows for good load transfer as well as efficient crack deflections due to low shear strength (Naslain, 1995) and cohesive fractures (see Fig. 3).

In order for crack deflection to take place effectively in the interphase, the energy of fiber-matrix bond breakage is about four times lower than the breaking energy of a fiber (Budianski *et al.*, 1986). Otherwise, the crack would propagate through the CMC material causing catastrophic brittle fracture. However, the main weak point of pyrocarbon interphases is its high sensitivity to oxidation at temperatures in excess of 400°C. In the presence of oxygen, the oxidation reactions of pyrocarbon are similar to those of carbon (Filipuzzi *et al.*, 1994). Another interphase material, increasingly used for its much better resistance to oxidation is boron nitride (BN) (Morscher, 1997). Despite poorer mechanical strength and less energy-dissipating adhesive breaks, it oxidizes very little at temperatures below 800°C, and upon oxidation forms a healing oxide B_2O_3 , rather than gaseous products alone leading to active oxidation.

Further, the idea of multiplying and extending the crack deflection zones led to development of architected interphases with the superposition of layers of different natures (i.e., sequences) between the fiber and the matrix. Diefendorf and Boisvert (1988) and Boisvert *et al.* (1989) have thus added multilayer carbon/silicon carbide (C/SiC) (liquid deposited between fibers SiC and a SiC matrix) which considerably improved the toughness of SiC/SiC composites. This concept of multilayered interphases went up to the development of sequences at a nanometric scale (Bertrand *et al.*, 2000) (See Fig. 3). Heraud *et al.* (1989) then considered the total sequencing of the matrix within a bidirectional SiC/SiC composite by inserting more compliant materials such as pyrocarbon or boron nitride by chemical vapor infiltration. The formation of a sequenced matrix by interposing one or more weaker layers rigidity leads, according to the authors, to (1) the delay of the initiation of fracture, (2) the increase in fracture energy and (3) the decrease in the sensitivity of the composite to the notch. While mainly found in oxide/oxide composites, a porous material is able to deviate a crack with a branching effect (Fig. 3).

Mechanical Behavior Under Tensile Loading

A ceramic matrix composite subjected to a uniaxial tensile test in the direction of the fibers exhibits three successive damage domains (Naslain, 1985, 2004; Bansal, 2005; Chawla, 2012). These are summarized in Fig. 4. In the first linear elastic domain, the material does not undergo damage, and returns to zero strain when unloaded. The modulus of the composite E_c can be estimated from the modulus of the matrix E_m and that of the fibers E_f by a simple law of mixtures (Eq. 1) (In Fig. 4,

Fig. 3 Deflection of a matrix crack by an interphase. Reproduced from Bertrand, S., Droillard, C., Pailier, R., Bourrat, X., Naslain R., 2000. TEM structure of (PyC/SiC)_n multilayered interphases in SiC/SiC composites. *Journal of the European Ceramic Society* 20 (1), 1–13.

Fig. 4 Relation between the interfacial bond strength and the mechanical behavior of a CMC under tensile loading.

$E_m > E_f$ for the composites), by considering only the fibers in the considered loading direction and without curvature (or negligible curvature):

$$E_c = E_f \cdot V_f + E_m \cdot V_m \quad (1)$$

with:

V_f : filament content or fiber volume (volume fraction)

V_m : matrix content or matrix volume (–volume fraction)

thus $V_m + V_f = 1$

The second domain begins with matrix cracking. These cracks are often created in angular areas where macro-porosities are present in the composite and act as sources of stress concentration. The behavior then becomes non-linear because of the multi-cracking of the matrix. Finally, the last field appears when the state of matrix cracking is saturated. The contribution of the matrix is then negligible and the mechanical behavior is controlled solely by longitudinal fibers: the load being then entirely taken up by the longitudinal fibers. This feature is verified by the very close values between the modulus of the composite and that of the fibers multiplied by the volume fraction of the longitudinal fibers (according to the rule of mixture). The ultimate breakage is thus dictated by the fibers, with a first phase of stable rupture, then a second unstable phase (Lamon, 2001). As the load increases, some fibers (probably because of presence of defects) individually break, resulting in transfer of the load to the surviving fibers. The final break occurs when a critical number of fibers has broken, and the surviving fibers cannot withstand the load increment generated by the breakage of an additional fiber (Lissart and Lamon, 1994).

The extension (range of strains) of these successive steps is directly dependent on the quality of the link between fiber and matrix which consequently, must be perfectly controlled (see Fig. 4). Indeed, if this connection is too weak, fiber/matrix decohesions will be very important: the stress-displacement curve then presents a stress plateau, with complete load transfer on almost all the length of fibers. If the bond is strengthened (but not too strong), on the contrary, the cracks may be deflected on a shorter length along the fiber surface with a highly efficient load transfer. Non extended damaged zones continue into the composite and new matrix cracking can still occur for increasing loading. Multi matrix cracking is then observed and the matrix contributes only partially to support the load up to failure. The decrease in local stiffness along the stress-strain curve becomes regular and the level of failure stress is higher. A well-adapted bond is essential to obtain the desired damageability.

In Fig. 5, stress-strain curves are drawn for each different fiber-matrix bond strength (Droillard *et al.*, 1995; Rebillat, 1996; Naslain, 1998). The changes in slope are not as neat as in Fig. 4 but they can be identified. The level of the elastic limit is very low (around 0.05%) with no evidence (at this scale) of an influence of the interfacial bond strength. For the SiC/SiC composite with a weak interface bond strength, the saturation of matrix cracking occurs at a strain a little lower than 0.4% and further, the fibers sustain almost by themselves the loading up to failure. Thus, the failure stress is close to the product of the volume fraction of fibers and their failure stress. Conversely, for the SiC/SiC composite with an optimized intermediate interface bond strength, no plateau is visible on the stress-strain curve and the matrix participates to the support of a part of the load up to failure. A much higher level of failure stress is then reached.

During a tensile test, unloading/reloading cycles interposed during a tensile test form hysteresis loops which gives access, among other things, to the evolution of the modulus, to residual strains and the energy dissipated during these cycles, as shown in Fig. 6(a). Indeed, the shape of unloading/reloading hysteresis loops for a composite material are uniquely different compared to a metallic material. Opened hysteresis loops show that the phenomenon of energy dissipation is responsible for this behavior, although no damage is generated during such an unloading-reloading loop. This energy dissipation is linked to sliding and friction phenomena at the various friction interfaces of the material, especially between debonded longitudinal fibers and matrix. The dissipated energy due to friction is not the same during unloading and reloading due to a change in the sequence in the steps of fiber sliding (Peres, 1988; Lamon, 2001). Consequently, the cycles are very narrow for small deformations (little dissipated energy) and larger with greater damage to the material. For example, the width of loops is much larger when: (1) the fiber/matrix bond strength is weaker, (2) the lengths of sliding are greater and (3) the matrix crack spacing is greater (see Fig. 6(a)).

Monitoring damage evolution of SiC/(Si-B-C) composites using electrical resistivity: Crack-density based electromechanical modeling. *Acta Materialia* 124, 579–587.

Acoustic emission (AE) has proved to be an interesting technique for quantifying matrix cracking as well as predicting times to rupture (Morscher, 2004; Maillet *et al.*, 2012; Moevus *et al.*, 2008). However, with this technique, it is necessary to monitor the material during all of its service life, because it is sensitive to transitions of states (crack creation for instance), and it cannot evaluate a damage state at zero stress without previous monitoring, which would be useful for maintenance. The recorded acoustic signal in the case of a cumulative count mode (see Fig. 6(b)) shows (1) a signal starting with the first matrix cracking, (2) an increasing cumulative signal related with the progressive damage propagation and (3) a slowing in acoustic emission when the matrix becomes fully cracked.

Many other non-destructive evaluation techniques (NDE), such as acousto-ultrasonic, X-ray or thermography, allow damage detection in various types of materials including CMCs (Bertrand *et al.*, 2017; Jumel *et al.*, 2001). However, most of these techniques (1) often require that the components should be taken out for testing (needing long times), and (2) are more efficient for the detection of out-of-plane flaws (such as delamination) than the detection of typical thin transverse cracks perpendicular to the surface observed in CMCs. Electrical resistance has proved to be a pertinent measure of the damage state for various materials such as carbon fiber-reinforced polymer composites (CFRP) (Schulte and Baron, 1989), particle reinforced polymer composites (Ruschau *et al.*, 1992), and more recently in civil engineering materials (Ranade *et al.*, 2014; Vesely *et al.*, 2015). This technique has the advantage of discrete measurements without damage monitoring, as it provides a physical property of a material at a given time instead of recording transitions of states, as it is the case with AE (see Fig. 6(b)). At room temperature and at high temperature, the measurement of residual resistances (during loading and even at zero stress) is higher than the initial resistance, and increases with the maximum applied stress. This feature has been related to greater damage accumulation, reflected either by the length of the debonded interphase or the density of matrix cracks, depending on which constituent is the best electrical conductor (Smith *et al.*, 2011, 2008; Morscher *et al.*, 2014; Simon *et al.*, 2017a,b). The resistance monitoring can therefore give access to information concerning different damage modes.

Finally, the observation of the failure faces of a composite shows that the fibers don't break on the same plane as the matrix. (see Fig. 7). Fiber pull-out or voids in place of fibers are visible on the failure surfaces. A fiber breaks when locally the failure stress of the fiber is overcome. This critical failure stress is related to the local overloading due to the presence of a defect inside the fiber. It is well known that the defects are randomly distributed and this breaking can only occur along a damage zone. The combination of these factors explains the complex appearance of the failure surface. The average pull-out length becomes respectively an indicator on the fiber/matrix interfacial bond, i.e., weak bonding leads to long pull out lengths while strong bonding leads to shorter pull out lengths. For example, it is shorter when the debonded lengths are lowly extended and respectively, when the fiber/matrix bond is strengthened.

Fiber/Matrix Interfacial Shear Stress

The deviation of a transverse crack by the interphase generates debonding between fiber and matrix over a specific length (see Fig. 8). Thus, in the vicinity of the crack, the matrix is locally unloaded, causing an interfacial slip, governed by the interfacial shear stress τ , as the fiber becomes overloaded (Fig. 8(a)). During unloading and reloading, the fiber elongates in reaction to the stress while the unloaded matrix deforms much less. This generates sliding with associated friction and wear, because of the roughness at the interfaces (see Fig. 8) (Evans *et al.*, 1991; Evans and Zok, 1994).

Load transfer along fiber/matrix interfaces is controlled by the ratio of interfacial shear stress, τ , to fiber radius R . As shown in Eq. 2:

$$\frac{d\sigma_f}{dx} = \frac{2\tau}{R} \quad (2)$$

where σ_f is the stress to which the fiber is locally subjected and x the length along the fiber. In the case of an interface where relative displacements between fiber and matrix are possible, if τ is considered constant (Arnault, 1989), the load - distance profiles are linear along

Fig. 7 Failure facies of a C/C composite under tensile loading. Reproduced from Bertran, X., 2013. Comportement en oxydation de matériaux composites C/C dans des applications aéronautiques à faible température. PhD Thesis. University of Bordeaux.

Fig. 8 Representations (a) of the stress-length relationships along a debonded and (b) of a matrix crack in propagation and the mechanisms of energy dissipation involved.

the debonded length (see Fig. 8(a)). With weakening of the interface, the longer is the debonded and overloaded fiber length, and the higher is the probability of finding a defect of critical size.

The interfacial shear stress, τ , also has an important influence on the cracking step. With low τ , the matrix will be unloaded over a longer length (Fig. 8) and any crack creation is prevented on this same length. The result is a more significant distance between the matrix cracks and much larger crack opening, referred to as “residual displacement” in Fig. 8(a). (Rouby and Reynaud, 1993; Curtin, 1991).

It is thus well-known that matrix cracking is a damage mechanism inherent to this type of material. Under oxidizing environments, this feature can be a critical parameter with the formation of crack paths toward fibers and interphase aiding diffusion of oxidizing gaseous species (O_2 , H_2O) and contributing to the dramatic reduction in mechanical properties (Glime and Cawley, 1995; Lamouroux *et al.*, 1999; Christin, 2002; Casas and Martinez-Esnaola, 2003; DiCarlo *et al.*, 2004; Rebillat, 2014). This is why it is preferred that mechanical damage generates numerous thin matrix cracks rather than a few large cracks (see Figs. 4 and 5).

Manufacturing

Choice of Manufacturing Process With Respect to Required Properties

Depending on application, the temperature of use and the life time are generally reciprocally related. For lower temperatures applications around 800°C , such as in aircraft engines, 60,000 h can be required. However, in space propulsion, the material has to last for around 3 min at temperatures above 2000°C (see Fig. 9). In addition, applications may need thermal insulation materials while others require a high thermal conductivity. Whatever the applications, today, most of the industries design their parts such that they operate within the linear elastic domain under thermomechanical loading. Increasing the elastic limit therefore becomes the singular challenge. These properties are strongly linked to the materials properties, such as purity, crystallinity and porosity. Main of these characteristics at the macroscopic scale of the composite are imposed by the choices of constituents but also through the distribution of the matrix inside the fibrous preform (Table 1). The method for manufacturing matrices imposes a major part of the final properties of the matrix and consequently the composite.

The traditional process for developing the matrix is gas infiltration (CVI for Chemical Vapor Infiltration); the phases obtained being pure and crystallized (or at least controlled). However, gas infiltration is a long and expensive process and several other

production routes, known as liquid routes (PIP for Polymer Impregnation and Pyrolysis and MI/RMI of silicon for Melt Infiltration/Reactive Melt Infiltration) and slurry routes are possible.

Fabrication by Gasous Route: Chemical Vapor Infiltration (CVI)

CVI gas production processes were developed in the 1960s in the United States and Russia to fabricate ceramic matrix composites. There are different variants: isothermal, pressure gradient, pressure pulsed, pressure gradient temperature, by heating (the Kalamazoo process or film boiling) (Golecki, 1997; Langlais, 2000). We will limit this chapter to the LPCVD (Low Pressure Chemical Vapor Deposition) and I-CVI (Isothermal & Isobar Chemical Vapor Infiltration) processes.

The mechanisms of deposition are similar in both CVD and the CVI processes and consists of depositing a solid on the hot surface of a substrate by reaction/decomposition of gaseous precursors. The basic phenomena comprise: (1) mass transfer in gas phase by diffusion and convection, (2) gas phase homogeneous chemical reactions and (3) surface chemical reactions with deposition (Langlais, 2005) as indicated in Fig. 10.

Various compositions of deposited materials are made possible by changing the nature of the gaseous precursors as given in the examples below:

with $H_y = CH_4, C_3H_6, C_3H_8X = F, Cl, Br$

From a kinetic standpoint, any of the mass transfer or chemical reactions as well as deposition can be rate-controlling. These overall processes are guided by thermodynamics and controlled by chemical kinetics or diffusion. CVD thus involves complex physicochemical processes which bring together homogeneous and heterogeneous transport phenomena and chemical reactions, that are in competition.

The CVI process involves growing a solid deposit within a porous material in order to densify it (Naslain, 2004; Langlais, 2005; Vignoles, 2015). Fig. 11 schematically shows deposit growth within a cylindrical pore. However, the typical assembly of fibers and rovings creates a network of porosity of complex shape with a large pore size distribution from a nano scale up to 500 μm average diameter. This

Fig. 10 Schematic view of the different stages of transport and homogeneous and heterogeneous chemistry in CVI.

Fig. 11 Schematic of the development of a gradients deposit thickness along a pore in function of the temperature during the CVI process.

becomes the additional difficulty involved with CVI compared to the CVD process. Indeed, the supply of precursors no longer occurs only through the boundary layer but also within the porous medium to bring reactive species deep inside the fibrous preform.

The thin interphase layer constituting the interphase is commonly deposited by this method, prior to infiltration by the matrix material. For longer process times, closure of the pores entrances on the surface generally appears when there is a greater consumption of the gas precursors close to the outside surfaces of the preform, before reactive gas have time to diffuse into the fibrous preform (Fitzer and Gadow, 1986; Fedou *et al.*, 1993) (see Figs. 10 and 11). With the decrease in the opening of the pores following deposition, the resistance to gas transfer into the preform increases. The combination of these phenomena leads to differences in composition between the gas phase in the gaseous environment and within the porous network of the preform. It can even lead to changes in the mechanism of deposition between the outer surface and interior of the preform. Thus, on the surface, the deposition regime is limited by chemical kinetics, while within the preform, it is diffusion which limits the supply of reactive species, leading to a deposition régime limited by mass transfer (Golecki, 1997). All of these phenomena explain the differences of deposited thicknesses between the surface and interior of the preform. So, to get a delayed closing of pore entrances, it is recommended that the processing temperature is decreased in order to reduce the consumption rate at the surface as indicated in Fig. 11, and to lower the working pressure to increase the free diffusion path length inside the preform.

In the complete process, the preform is located within tooling to hold the different layers of fabrics. The whole is then placed in a hot wall reactor at temperatures between 900 and 1100°C and at reduced pressure ($P < 10$ kPa) (Golecki, 1997) (see Fig. 12). During this process, the interphase and matrix deposits are carried out successively using precursors gaseous of different natures.

Fig. 12 Schematic view of the different stages for the fabrication of CMC by the CVI process. Reproduced from Naslain, R., 2004. Design, preparation and properties of non-oxide CMCs for application in engines and nuclear reactors: An overview. *Composites Science and Technology* 64, 155–170.

For example, SiC generally has a columnar growth, along the [111] crystallographic direction. The growth of coatings starts from all the developed accessible surfaces (the walls of voids) and stops once the surfaces of coatings meet each other in the narrow spaces. Locally, gas access into voids is prevented across the preforms and large voids remain at the end of the densification step as indicated in Fig. 13. Pores with angular shapes are visible (indicated by arrows). It is from such pores that matrix cracks are generated at low levels of loading.

To delay premature closure of pores, thermal gradients can be introduced into the preform. Forced flow through the preform are may or may not be additionally introduced to enhance the diffusion of gaseous precursor species and/or to reduce reaction rates (Besmann *et al.*, 1991) (see Fig. 14).

To conclude, the main advantages of I-CVI are: (1) limited fiber degradation (low T, P process), (2) high quality matrix deposition with variety of composition and microstructure (crystallinity), (3) near net shaping of composites (self standing preform), high flexibility (different preforms) and limited handling (low man-power cost).

However, the level of residual porosity remains relatively high at 10%–15%. Such a high level of porosity contributes to a lower elastic limit and reduces the thermal conductivity. According to the specifications for deposited materials, these composites should possess enhanced structural, chemical and mechanical stabilities. However, common process times for a densification of a fibrous preform, can require durations as long as a few hundred hours.

Fabrication by a Liquid or Semi-Liquid Route Infiltration

Slurry – Infiltration/hot pressing sintering (SI/HPS) route

The slurry infiltration manufacturing route is a pioneering process used to fabricate glass and glass-ceramic composites which has recently been revisited and adapted for refractory covalent matrices. The goal is to fill all the pores of a fibrous preform with the slurries of the material(s) of the future matrix.

The liquid precursor is a stable suspension (slurry) of fine particles in a solvent with fugitive binders and additives.

The main steps for the whole process are shown in Fig. 15 (Prewo, 1986; Bansal and Setlock, 2001) and can be listed as:

- Tow (or tape, woven, preform) impregnation to get a green prepreg
- Hot pressing for consolidation ($T > 1000^{\circ}\text{C}$)

Fig. 14 Enhanced CVI processes (matrix – blue, void – white).

In the slurry, the proportions of powders of different materials can be easily regulated, to obtain a variety of compositions. However, it is necessary to be able to prepare stable suspensions to get homogeneous impregnation and sufficiently high fill rates. Many parameters can be taken into account such as: (1) the nature of the solvent, (2) the pH of the solution, (3) the use or not of a dispersant (often a polymer), (4) the size of the particles (such that they are thin/small enough to move inside fiber bundles) and (5) the final viscosity of the suspension.

Several methods have been considered to introduce the powder into the inside of the fibrous preform:

- Simple impregnation methods which consist of coating each layer of fabric by suspension, before stacking (Prewo, 1986; Bansal and Setlock, 2001);
- Methods of infiltration (Slurry Infiltration) where the suspension is directly deposited on the fabric, possibly aided by vacuum (Levi *et al.*, 1998);
- Injection methods, including RTM (Resin Transfer Molding) processes or Flexible Injection (Scola *et al.*, 2019), which are based on the introduction of the matrix into a mold containing the fibrous reinforcement in order to force the impregnation in to the reinforcement;
- Other more atypical methods such as colloidal processes (Simon, 2005) or VibroIntrusion (Haslam *et al.*, 2000).

Fabrication of fiber-reinforced celsian matrix composites. *Composites Part A: Applied Science and Manufacturing* 32 (8), 1021–1029.

Fig. 16 Vacuum impregnation process of preforms by a slurry.

In addition, vacuum can be applied to the preform to enhance the impregnation step by a slurry or can be used to aspirate submicron powders (ASPs) through the preform.

Vacuum transfer impregnation is a classic method used for the impregnation of porous composites (see Fig. 16). The slurry or slip is allowed to slowly flow down on to a preform, maintained under vacuum. In a pore, during impregnation, the powder is homogeneously distributed in the solvent. After drying, the solvent evaporates and the particles form a layer on the walls of the pores. If the suspension has a low solids loading, large voids appear. This can be avoided with the use of a slip which has a sufficiently high powder loading. The development of such very concentrated slips is thus required for this technique. Vacuum transfer impregnation has the advantage of allowing the impregnation of parts with complex geometries, but the process is long and complex to implement.

Impregnation by the absorption of submicron powders, shown schematically in Fig. 17, is a technique allowing the introduction of powders into a fiber preform by applying pressure to the upper face of the sample, while the lower part is connected to a vacuum chamber. This method forces a powder suspension through the sample. A filter retains particles within the preform while the liquid passes through. Thus, the particles remain trapped within the pores until they are completely filled. The major drawback of this process remains the residual porosity within the powdery medium after impregnation of the powders. The use of a second process to improve densification is usually necessary, but its efficiency depends on the ratio of remaining open porosity.

Depending on the complexity of the geometry and/or the nature of the fiber, pressure and/or a high temperature cannot be used to enhance the sintering. Also, hot pressing is limited, in terms of applied pressure, on a fibrous preform made up of long fibers. This is so processing occurs without breaking fibers and/or introducing a very high level of residual stresses inside the different constituents. Consequently, when a pressureless sintering is only used, the amount of residual porosity can exceed 10% (see Fig. 18) (Prewo *et al.*, 1986; Rahaman and De Jonghe, 1987; Raether, 2013; Ben Ramdane *et al.*, 2017). Since all the matrix is porous with pre-existing processing cracks, the extended thin porous network itself causes deviations in matrix crack paths with a real branching effects

Fig. 17 Schematic diagram of APS: (a) before impregnation, (b) during impregnation, the suspension settling in the pores, (c) after impregnation, the pores are filled with the powder.

Fig. 18 Cross Section of a Nextel™ 610/alumina weak matrix composite. Reproduced from Ben Ramdane, C., Julian-Jankowiak, A., Valle, R., *et al.*, 2017. and toughening (Zok and Levi, 2001). The contribution of such a matrix to the level of the mechanical resistance of the composite remains modest and the non-linear domain can be reduced, depending on the fibrous architecture (Levi *et al.*, 1998).

To get a dense matrix with a low residual porosity (< 5%), a liquid phase aid is required during HPS (hot pressing sintering). With composites possessing a hermeticity, complex pieces in oxide/oxide composites are manufactured as distributors for exhaust systems (Raether, 2013) and parts in aircraft engines (e.g., Nozzle, Mixer, Center Body, and Engine Core Cowl) as indicated by Gonczy (2015). For non-oxide composites, a well known process is named the Nano-Infiltration Transient Eutectic Phase (NITE) process and involves the infiltration of SiC weaves and rovings by a nano-slurry. The manufacture of dense SiC ceramics is generally achieved by high sintering temperature ($\sim 2000^{\circ}\text{C}$) and/or under pressure ($> 30\text{ MPa}$) using SiC nanometric powder containing additives sintering (carbon, boron, $\text{Al}_2\text{O}_3/\text{SiO}_2$, $\text{Y}_2\text{O}_3/\text{Al}_2\text{O}_3$ etc.) (Dong and Katoh, 2002a).

To conclude, the main advantages of the slurry cast process are: (1) a generic process relying on well-known technologies, (2) a residual porosity able to be reduced down to < 5% (hermeticity), (3) a short processing time, (4) near net shaping, and (5) purity and crystallinity. depending of those of the introduced powders.

According to reported specifications, these composites should possess a reduced elastic limit and thermal conductivity values as porosity levels increase. Their thermal stability is also affected by the purity of the constituents and/or the introduction of sintering aids.

Impregnation by an organic precursor of the matrix (PIP)

Polymer impregnation (PI) and pyrolysis (P) is a generic processing technique, which can be used to fabricate CMCs when a fusible (or soluble) polymer precursor of matrix is available. The PIP technique therefore makes it possible to control the composition of the matrix, due particularly to the diversity of organometallic precursors available.

Fig. 19 shows a schematic representation of the PIP process. It consists of: (1) impregnating a polymer precursor into the preform, (2) crosslinking this precursor in situ and (3) pyrolyzing it in order to form a ceramic matrix (Sato *et al.*, 1992; Dong *et al.*, 2002b; Kotani *et al.*, 1999). Numerous PIP cycles must be repeated until the desired densification level is achieved in order to fill the volume shrinkage resulting from the pyrolysis of the precursor (Ziegler *et al.*, 1999; Jones *et al.*, 1999).

Fig. 19 Schematic of the PIP process.

The pre-ceramic precursors are selected according to their chemical composition, their viscosity, the crosslinking conditions, the ceramic yield, the volume shrinkage during pyrolysis, the microstructure of the matrix obtained or their stability (at temperature, in air and in high humidity) (Greil, 2000; Mutin and Boury, 2001). For example, many polymer precursors possessing a high ceramic yield can be listed as:

phenolic or furanic resin, pitch	carbon
polycarbosilane (PCS)	SiC
perhydropolysilazane (PHPSZ)	Si ₃ N ₄
polyalkylborazine (MAB)	BN
poly-borosilazane (PBSZ-Me)	Si-B-N-C

Different techniques can be used to impregnate the preceramic resin into the preform. The most widely used are: (1) impregnation under reduced pressure, which consists of creating a primary vacuum in an enclosure containing the sample immersed in the resin and (2) the RTM (resin transfer molding) process where the resin is injected under pressure into a preform placed in a mold (Naslain, 2004). A good wetting of the preform by the resin is essential to impregnate a maximum material and make this step efficient.

The cross-linking step (or curing) conditions the progress of the pyrolysis. It allows the formation of bonds between the polymer chains so that mainly methyl groups and heteroatoms (hydrogen, oxygen and nitrogen) are evacuated during pyrolysis. Crosslinking can be carried out thermally, by oxidation in air, by chemical additives, or by irradiation depending on the polymer used.

The pyrolysis step transforms the network obtained by crosslinking into a ceramic. The yield and composition of the final ceramic material depend first on the composition of the precursor, but also largely the crosslinking conditions and pyrolysis. The application of isostatic pressure in an autoclave during pyrolysis can increase the yield of residual condensed phase. It is usually done by conventional heating, but there are also heating processes involving laser pyrolysis, irradiation, or microwave. In general, pyrolysis under an inert atmosphere takes place according to the following steps (Mutin and Boury, 2001):

- (1) degradation, loss of organic compounds (300–600°C);
- (2) mineralization, loss of hydrocarbons and hydrogen (400–1000°C);
- (3) decomposition, loss of CO, SiO, N₂.

However, the composition and crystallinity of the ceramic residue depend on the temperature of pyrolysis, the rate of temperature rise, but also the atmosphere of pyrolysis. For example, the pyrolysis of a polycarbosilane can give a SiC matrix with free carbon under argon, but only SiC under hydrogen (Yajima *et al.*, 1976).

Many dimensional changes occur during polymer-ceramic conversion for bulk component fabrication (Greil and Seibold, 1992; Greil, 1998, 2000) (see Fig. 20). So, the main drawback is the volume shrinkage observed during pyrolysis, with a volume decrease up to more than 50% (Bertran, 2013) (see Fig. 21). The repetition of PIP cycles makes the process long (Ziegler *et al.*, 1999) and expensive, especially since polymer precursors are relatively expensive. This is why this densification technique is still not widely used industrially.

As indicated in Fig. 20, the pre-ceramic resin can be loaded with ceramic, non-reactive powders (C, SiC, Si₃N₄), in order to improve the desired properties of the composite, or else to decrease the volume shrinkage (Kotani *et al.*, 2003; Lee and Kim, 2009; Zhu *et al.*, 2008). Nevertheless, the addition of these charges considerably increases the viscosity of the infiltrant, to the detriment of the impregnation of the preform.

Fig. 20 Volume changes of polymer-ceramic during pyrolysis without and with reactive charge.

To conclude, this process is based on well-known technologies. The PIP-residue is generally amorphous but can be sintered or crystallized with post heat treatments. It is well suited to complex composition and does not require heavy investment. However, the weight loss/shrinkage during pyrolysis may require filler addition and/or multiple PIP sequences. These composites can possess a high residual porosity.

Like the liquid infiltrated CMCs, these composites should possess elastic limits and thermal conductivities which are controlled by porosity levels and their thermal stabilities are related to the impurities present in the polymer precursors.

Hybrid Processing Route or the Use of the MI/RMI Process

Presentation of MI/RMI process and the hybrid route

The previous processes discussed have many drawbacks with a too high a residual porosity level. To get a matrix close to 100% dense, combined processes are generally required which allow complete filling of voids with condensed material as indicated in Fig. 22. To reach such a level of densification, impregnation with a molten material is advised. This material should have a high melting point, allowing to get it (1) in a liquid state for the impregnation at very high temperature, compatible with the thermal-stability of the preform and (2) still in a solid state at high temperature, according to future application temperature requirements. In the case of a metal, the process is named as MI/RMI: Melt infiltration/Reactive melt infiltration. The infiltration temperatures must be higher than the melting temperature of the metal or alloy used, for example: (1) formation of SiC by infiltration of Si, $T_f = 1415^\circ\text{C}$ (Krenkel, 2004), or (2) formation of ZrC by infiltration of Zr, $T_f = 1850^\circ\text{C}$ (Quet, 2007). The melt metal is introduced inside a preform, generally partially filled with by PIP/slurry processing (see Figs. 23 and 24). This infiltration is termed reactive when the metal is consumed by reaction with this filler material to give a more refractory compound (ceramic (for example, carbide, as previously mentioned, by reaction with carbon) or intermetallic).

Historically, the first work on the infiltration of molten silicon dates back to 50 years ago with that of Popper *et al.* on the reactive sintering of SiC (Popper and Davies, 1961). The process was subsequently optimized, then produced industrially by Ford (KT SiC) and the Atomic Energy Authority (REFEL SiC) (Forrest *et al.*, 1972) in Great Britain and Norton Ceramics (NC 435) in the USA. General Electric introduced in early 1970s, the impregnation of ceramics reinforced with carbon fibers (Hillig *et al.*, 1975). The liquid silicon infiltration technology itself has been the subject of numerous patents from General Electric (Brun and Morrison, 1993; Hillig and Morelock, 1980). The liquid silicon impregnation process has been applied to SiC/SiC composites from the beginning of 1990s (Luthra *et al.*, 1993).

Of those routes developed only two have been selected for industrialization (Luthra and Corman, 2001): one path known as “prepreg” and the other “slurry cast” (shown schematically in Fig. 23). The “prepreg” route begins with the deposition of an interphase of doped boron nitride silicon, then a layer of SiC, on Hi-Nicalon or Sylramic fiber bundles or just the deposition of SiC interphase. The bundles are then “dipped” in a slip containing SiC particles, particles of carbon, organic binders and a solvent, then are wound around a mandrel. After drying, the bundles are cut then spread and compressed to form a porous preform. At this stage the preform can be cut according to the desired final geometry. Infiltration by liquid silicon, according to one of the different processes developed by G.E., takes place after an intermediate debinding step at 500°C allowing the decomposition of organic carbon containing products.

The second path known as “slurry cast” differs from the previous one in that the fibers are first woven or braided and then compacted to form a 3D fibrous preform. An interphase identical to the previous one (BN or BN (Si) + SiC) is deposited by CVI. The preform, thus consolidated, is impregnated with the same slip as before then densified by the liquid silicon.

In the case of a liquid silicon infiltration, the conditions used are fairly standard, namely: a temperature below 1450°C , a reduced pressure less than 5×10^2 Pa and an impregnation time of 10–30 min (Brun and Morrison, 1993; Hillig and Morelock,

Fig. 21 Electron micrograph of the cross section of a C/C composite after 1 PIP cycles at different magnifications: (a) whole composite and (b) in a bundle. Reproduced from Bertran, X., 2013. Fig. 22 Combination of processes to get a dense matrix in CMC.

1980). The silicon is brought into contact with the material by means of a nozzle (Luthra and Corman, 2001; Luthra *et al.*, 1993). It can also simply be put on the top of the preform (Luthra *et al.*, 1993) as indicated in Fig. 24. The use of a nozzle reduces the post infiltration machining phase by reducing the excess silicon on the surface of the material.

The essential parameter for the infiltration of a preform is the wetting of the substrate by the molten metal which is then directed inside the preform via the capillary driving forces. Various parameters influence the state of densification and the final composition of the composites produced: the infiltration time, the infiltration temperature, the porosity of the material to be densified, and the size distribution of the pores.

Fig. 23 Impregnation process, prior to the MI step.

Fig. 24 Schematic of the liquid silicon impregnation process of a fibrous preform, impregnated with a filler material.

To help in the prediction and understanding of the infiltration process, Washburn (see [Mondon, 1996](#)) introduced a mathematical expression allowing the determination of the penetration as a function of time, of a fluid in a porous medium defined by parallel pores and constant section. This simple law is often used to understand the global kinetics of impregnation of a preform. However, the application of this law is limited to short times, to low heights (thus negating the need to account for the forces of gravity) and identical cylindrical pores. Here, the porosity is summarized as an average pore size that is assumed to represent and gather the large distribution of pore distribution in porous structure of fibrous composites.

Specificities of the RMI process with melted silicon

There are many ways possible to develop a porous carbon inside the porosity of the preform (pitch, wood, phenolic resin, aerogels, pyrolysis of an organic binder ([Hucke, 1966](#))).

The wetting of liquid silicon on the carbon is said to be reactive due to a chemical reaction between solid and liquid and the formation of a new phase at the solid/liquid interface. The chemical reaction between carbon and silicon leads to the formation of β -SiC, with an enthalpy of formation (ΔH_{298}°) equal to $-69-73 \text{ kJ mol}^{-1}$ ([Fitzer and Gadov, 1983](#)). This reaction is exothermic and its degree depends on the nature of the carbonaceous substrate ([Sangsuwan et al., 1999](#); [Singh and Behrendt, 1995](#)). Carbon has a solubility in liquid silicon of less than 1 at%, compared to $10^{-2}-10^{-4}$ at% C in solid silicon over a temperature range up to 1800K. The diffusion of carbon in liquid silicon is very fast and depends on temperature ([Pampuch et al., 1986](#)). The material

produced has a microstructure of α - and β -SiC grains forming an interconnected network, in which the remaining volume is occupied by free silicon.

However, the volume of the solid phase occupied by a carbon atom doubles when it is transformed into SiC. Thus, the open porosity of carbon must be large enough to allow the volume increase due to this reaction in presence of silicon. If this is not the case, the access of the molten silicon to the inside of the preform is locally stopped prematurely by the formation of SiC, acting as a cork. This phenomenon is called “choking-off” (Hillig, 1993; Singh and Behrendt, 1994). Fitzer and Gadow (1983) have shown that the infiltration of carbon by silicon requires control of the microstructure and porosity of the initial carbon preform.

Hybrid route applied to SiC/SiC

In this manufacturing process, the fibrous reinforcement is first protected by a specific interphase. The whole is then coated with a SiC matrix, to protect the previous constituents from the diffusion of Si (Nannetti *et al.*, 2001). The material obtained is then impregnated with carbon fillers and/or SiC before being densified with liquid silicon. Generally, the production is done without applying an external pressure, but under vacuum, at a lower temperature than 1500°C (Luthra *et al.*, 1993) (see Fig. 24). The silicon impregnation ends the process and allows the formation of a matrix of SiC, more or less rich in silicon and silicides instead of the initial porosity. The final microstructure, in particular the residual silicon content, will depend on the nature of the constituents of the preform to infiltrate (e.g., grain size, porosity of the preform, non reactive SiC or reactive C, nature of the carbon filler, etc.). Silicon fills all open voids and notably macropores partly filled after impregnation by the filler (see Figs. 25(a) and 26). Many small closed pores inside bundles remain empty of silicon (Fig. 26). The residual porosity is essential linked to the latter voids. For example, if the initial porosity inside the preform is around 40%, it can be reduced to 20% after impregnation of SiC powder and less than 5%, after MI/RMI (Griesser, 2012) (again see Figs. 25(a) and 26).

Fig. 25 Liquid silicon impregnation of a SiC perform, impregnated with SiC fillers: (a) optimized impregnation and (b) impregnation prevented by gaseous release (free Si – white, SiC – different shades of gray, pores – black). Reproduced from Griesser, A., 2012. *Réalisation de matériaux composites à conductivité thermique accrue pour l’aéronautique*. PhD Thesis. University of Bordeaux.

Fig. 26 Detailed observation of a polished cross section on a liquid silicon impregnation of a SiC perform, impregnated with SiC fillers (free Si – white, SiC – different shades of gray, pores – black). Reproduced from Griesser, A., 2012. *Réalisation de matériaux composites à conductivité thermique accrue pour l’aéronautique*. PhD Thesis. University of Bordeaux.

Some authors attribute the presence of excessive porosity to the release of gaseous species within the preform during infiltration by liquid silicon (Morelock, 1986; Zhu and Shobu, 2001; Pan and Baptista, 1998; Griesser, 2012). A typical composite microstructure with such defects is shown in Fig. 25(b). These gaseous species are generated by the reduction of the silica layer present on the surface of the SiC grains, causing resistance to infiltration of the inside of the material, where they remain trapped due to faster infiltration at the outside of the preform. In order to prevent this phenomenon, a slowing of the infiltration is necessary in order to allow the evacuation of the gases produced before full densification of the material. This is possible by providing the silicon indirectly, or by designing a tool allowing the silicon to flow over the preform through a hole (Zhu and Shobu, 2000), either by using a nozzle (porous SiC bar) (Pan and Baptista, 1998), carbon wick (Morelock, 1986).

Furthermore, the presence of free silicon (from 10% to 65%, with reactive or non reactive fillers, or no fillers) within the ceramic composite limits its use to 1400°C and reduces the high temperature mechanical properties especially from 1200 to 1300°C, the extent of this decrease depending on the proportion of silicon (Zhou *et al.*, 1997). In order to allow their use at temperatures above 1400°C and to avoid reduction in mechanical properties at high temperature, the use of silicon alloys has been introduced to reduce the quantity of free silicon. The aim is to allow the precipitation of more refractory silicides to replace residual silicon (Van Rossum and Maex, 1995). Many alloys have been used and the most conclusive results having been obtained with those based on molybdenum (Singh *et al.*, 1991) for application for combustion chamber, and iron for application for brake disc applications (Gadow and Speicher, 2001). However, in order to allow good wetting of the alloy on SiC, an increase in the production temperature of around one hundred degrees above the melting point is sometimes necessary (Pan and Baptista, 1998).

To conclude, this process is faster and less expensive than CVI or PIP, since it allows very quick (less than an hour) and uniform to densification of the (macroscopic) porosities of fiber preforms (Jiang *et al.*, 2015; Tang and Hu, 2017). The need for production temperatures above 1410°C for several minutes requires the use of very stable SiC stoichiometric fibers. The major disadvantage remains the damage caused by the reactions between the molten metal and the C interphase and/or fibers (C or SiC), which can be all the more important as the processing temperature is high. The very reactive silicon with respect to interphase materials (C or BN) requires the prior deposition of a continuous protective layer (generally of SiC). Furthermore, the presence of residual metal after densification can have a negative effect on the mechanical properties at high temperature (in particular when the application temperature approaches the melting point of silicon where is able to flow through opening of cracks and/or react with and destroy with the carbon interphase and fibers by diffusion).

The mechanical characterization carried out on this type of material showed improvements in the linear domain and in the modulus of the composite, as well as better interlaminar properties, compared to a SiC/SiC composite developed by CVI (Corman *et al.*, 2003). Thanks to almost zero porosity composites, a marked increase in their thermal conductivity is also obtained.

Hybrid route applied to C/C

The application of the hybrid route to C/C composites was chosen to overcome their low resistance to oxidation and decrease their manufacturing cost. The first work was conducted within the German Aerospace Center (DLR) in Stuttgart, Germany for applications in the space field. These materials showed very good tribological properties (friction in particular), and their development continued with a view to producing high performance brakes (Krenkel and Fabig, 1995). Today, the goal of research in the area is to eventually use these materials in large amounts for automobile and plane brakes.

However, free silicon is observed within the matrix after silicon infiltration due to the filling of the porosities by the molten metal, (Kochendörfer, 1999; Krenkel, 2001; Schulte-Fischedick *et al.*, 2002; Lenz and Krenkel, 2012). This molten metal can oxidize, and creep when the composite is in use. Its distribution in the C/C composite is related to the matrix crack network developed during the pyrolysis of the carbon resin precursor according to the fiber/matrix strength bond (Kochendörfer, 1999).

Fig. 27 2D C-C/SiC composite after infiltration of liquid silicon on Cf/C preforms (Si – white, SiC – gray and C/C – black). Reproduced from Schulte-Fischedick, J., Zern, A., Mayer, J., *et al.*, 2002. Thermorphology of silicon carbide in C/C-SiC composites. *Materials Science and Engineering*: A332, 146–152.

After infiltration, formation of a SiC layer around the wires can be observed as well as the presence of carbon (fibers and protective coating) and residual silicon. Some carbon fibers can be partly consumed by reaction with the diffusing silicon along these cracks inside the composite as indicated in Fig. 27.

The RMI process is now used to densified C/C preform with Zr alloys (Tong *et al.*, 2012; Jiang *et al.*, 2014; Tong *et al.*, 2015; Chen *et al.*, 2016) or ZrSi₂ (Pi *et al.*, 2012; Zhang *et al.*, 2014) to get a protective UHTC matrix against oxidation at ultra high temperatures.

Conclusion

The properties typically required of long-fiber Ceramic Matrix Composites are: high mechanical strength, high thermal shock resistance, high stiffness, high toughness, high thermal stability, low density and high corrosion resistance, even at high temperatures.

SiC-matrix composites display a non-linear damageable-elastic behavior when loaded in tension and this is related to different damage phenomena at the scale of the microstructure (matrix microcracking, fiber-matrix debonding) and this damage is responsible for the decrease of stiffness. Failure occurs with some fiber pull-out at a strain depending upon the nature of fibers. Highest failure strengths are achieved when the interfacial bond is intermediate (not too strong) and crack deflection occurs in a diffuse manner in an anisotropic interphase. Such composites are tough and damage tolerant.

CMCs are fabricated by different processing routes depending on the nature of the matrix precursor: gas phase routes (CVI), liquid phase routes (PIP or RMI) and slurry routes, the matrix precursor being a gaseous species, a polymer or a molten element, or a particle suspension (slurry), respectively. The more recent research on a variety of modified processes are generally inspired by the well-known previously existing methods of manufacture. The major goals are still to reduce the cost and to shorten the fabrication time.

The final properties are strongly related to the microstructure of the constituents: purity, crystallinity, grain size, porosity. At the same time, each process allows only some of the required characteristics of microstructure to be realized. The combination of at least two simple methods makes it possible to reduce the disadvantages of each of them.

Thus, CMC, including C/C, composites have already applications in different fields. They are used to fabricate large size hot structures for space-craft and rocket engines for relatively short lifetime parts. Another promising application deals with aerojet engines and land-based gas turbines for cogeneration, where lifetime is of the order of several thousand hours at temperatures of up to 1200°C (if suitably protective environmental barrier coatings are applied). SiC/SiC composites seem to have a bright future in HT-nuclear reactors (fission or fusion) due to their low level of residual radioactivity after irradiation. Finally, C/SiC composites are used in advanced braking systems.

Introduction

Ultra-high temperature ceramic matrix composites (UHTCMCs) are the next generation of reusable materials for applications above 2000°C in aerospace, military and nuclear fields, where a combination of thermal shock and strong heat fluxes makes the materials choice very narrow. Typical components in UHTCMCs include heat shields and rocket nozzles (Binner *et al.*, 2019; Tang *et al.*, 2007a).

UHTCMCs are constituted of at least two essential elements integrated, e.g., a C or SiC fiber skeleton and an ultra-high temperature ceramic (UHTC) matrix. For extreme temperature applications, the fabric is preferably made of carbon fibers rather than SiC fibers, since carbon fibers have superior strength, modulus, thermal stability and lower cost as compared to SiC fibers (Huang and Young, 1995; Peterlik, 2014). However SiC fibers are preferable for long term applications in oxygen-rich atmospheres at temperatures below 1600°C (Fitzgerald and Shepherd, 2018).

The UHTC matrix can be in turn a composite, e.g., a UHTC phase amongst borides and carbides of the transition metals in groups IV and V combined with SiC or with multiple UHTC phases (e.g., ZrB₂/ZrC) (Kütemeyer *et al.*, 2015).

A composite that performs well does not require coating of the fibrous structure prior to composite processing nor a post-processing environmental external coating. Desired characteristics of these hybrid composites are a weak enough fiber/matrix interface to enable fiber pull-out at fracture, a dense matrix to hinder penetration of corrosive/oxidative gases and liquids and excellent thermo-mechanical properties at temperatures >1500°C, including strength and thermal shock resistance. Moreover, another property required is the capability to be re-used multiple times for short-time employ, exploiting the formation of an in situ external protective coating upon exposure to the service conditions of heat and oxygen (Vinci *et al.*, 2019a,b; Sciti *et al.*, 2018).

The purpose of the following sections is to give a concise overview of the state-of-the-art in the preparation of UHTCMCs classified under sintering or non-sintering routes. Then, the mechanical properties of the different groups of UHTCMCs are presented, together with the best thermo-ablative response materials available to date.

Preparation of UHTCMCs via Non-Sintering Routes

From the perspective of fabricating high performance UHTCMCs, researchers have been developing a spectrum of routes to enrich carbon fiber preforms with UHTC phases. There is a general consensus on the classification of various non-sintering methods: chemical vapor infiltration/deposition (CVI/D), precursor/polymer infiltration and pyrolysis (PIP), and reactive melt infiltration (RMI). All these methods have been readapted from the CMC processing technology to allow the introduction of UHTC phases into the fiber fabric. The UHTC phase concentration can be very different, depending on the process, and it has a remarkable impact on final density and mechanical and erosion resistance properties. It is important to note that a neat separation between various processes appears restrictive because a combination of them is often used.

Precursor/Polymer Infiltration and Pyrolysis (PIP)

Similar to the fabrication of polymer-matrix composites, fiber preforms are infiltrated with low viscous liquid preceramic polymers that will be converted into the ceramic matrix upon pyrolysis. Because of its simplicity, relatively lower processing temperatures and capacity to fabricate components with complex shapes, this technique is very cost effective compared to CVI. Most available preceramic polymers are carbosilane, polysilazane and polyxilosane resulting in SiC, SiCN(O), and SiOC-based composites. As far as we know, metal diboride precursors are not easily available on the market. The MATECH company claims to provide HfC and TaC precursors and therefore some researchers have started an intense investigation on the synthesis of new metal-containing polymers such as HfC/HfN precursors, namely poly(propyl)hafnizane (PPHZ) and poly(ethynyl)hafnizane (PEHZ), (Pope *et al.*, 2007). These can be converted into metal carbides, borides or nitrides by pyrolysis at high temperatures (Colombo *et al.*, 2010; Ionescu *et al.*, 2019; Terauds *et al.*, 2014). Currently, the most feasible way to introduce UHTC phases into these fibrous nets is impregnation of the preforms with a slurry containing the above mentioned preceramic polymers and the UHTC powders, followed by pyrolysis (Servadei *et al.*, 2020). The process is repeated several times to eliminate the residual porosity at most and the maximum processing temperature generally does not exceed 1500°C in order to limit possible fiber damage due to interaction with the reacting fluid (Heidenreich, 2014; Wu *et al.*, 2013). However, the custom-made nature of the metal-containing preceramic polymers often requires processing temperatures up to 1800°C to reach the desired yield. Hu *et al.* verified the detrimental effects of high-temperature on the microstructure and mechanical properties of C/SiC-ZrB₂ composites prepared by PIP, testing them at 1800°C and 2000°C (Hu *et al.*, 2010b).

Advantages of this technique include relatively low temperatures of processing and consequently prevention of fiber damage, fabrication of near-net-shape parts, and possibility of tuning the microstructure of the matrix as required by the temperature of pyrolysis. Despite some drawbacks, such as poorer mechanical properties of the composites compared to those produced by CVI, higher fabrication times and costs of production compared to RMI method (several weeks are needed for the multiple infiltration-pyrolysis cycles), PIP remains one of the most viable techniques for production of heat shields or propulsion parts for space field.

Chemical Vapor Deposition/Infiltration (CVD or CVI)

CVI or CVD are two variants of one largely used ceramic engineering process whereby the material constituting the matrix is deposited or infiltrated into fibrous preform using reactive gases at temperatures above 1000°C. Frequently, CVI/CVD have been widely employed for preparation of C and SiC matrices by methane and silane precursors, but have also been demonstrated to be capable of preparing UHTC composites. In this case, two main routes are possible. The conventional method requires UHTC slurry impregnation followed by CVI – CVD of C to close the porosity (Paul *et al.*, 2014, 2013b; Rubio *et al.*, 2018). Alternatively, MeCl₄, BCl₃H₂ (Me = Ti, Ta, Hf, Zr) in different ratios are used as MeB₂ precursors (Stinton *et al.*, 1988). Beside the requirement of complex and costly equipment, another disadvantage is the very slow deposition rate, leading to a large material energy input and high final costs, as well as the very limited infiltration depth. To overcome this issue, recently new radio frequency (RF) and microwave (MW) heating systems have been developed to decrease the manufacturing time, the main advantage being the deposition of material from inside towards outside, so that the deposition can proceed unhampered until the complete filling of the composite. However, large-size or thick parts are prone to non-uniform deposition and density gradients. In 2004 Sayir (Sayir, 2004) deposited UHTC onto a carbon fiber fabric by a CVI process using gas precursors of HfC, TaC and HfC/TaC. Tang *et al.* fabricated C_f/ZrB₂-SiC composites containing ~4 vol% of ZrB₂ as thin powder layers between fabrics and assessed the pronouncedly improved ablation resistance of the modified carbon composite upon exposure to an oxyacetylene torch flame (Tang *et al.*, 2007c). Likewise, Li *et al.* (2011) fabricated 2D-C_f/ZrB₂-SiC-TaC. The combination of CVI/CVD with PIP has been explored by some researchers for the preparation of UHTCMCs (Tang and Hu, 2017).

Advantages of this technique include relatively low processing temperature ranges, weak fiber/matrix interfaces, matrix microstructure control, and consequently, prevention of fiber damage and better mechanical properties compared to PIP and RMI. Near-net-shape components can be produced by CVI even with complex fiber architectures with 2.5D, 3D orientations. Despite the technological advances (RF and MW heating) CVI remains the process with the highest fabrication times and costs of production.

Reactive Melt Infiltration (RMI)

Reactive melt infiltration (RMI) is a consolidation technique based on the infiltration of molten metal, which reacts in the preform with a porous matrix to form a dense matrix with a higher melting point phase. The preform can be easily modeled into the desired shape before being infiltrated. Infiltration then takes place by capillary action or by applying external pressure and forcing the liquid to flow through the porous preform. Since metals of groups IV and V, e.g., Zr and Hf, have melting points of 1830 and 2130°C respectively, which would compromise the fiber integrity, infiltration of the carbon fiber preform is achieved with alloys which possess notably lower melting points and can be processed at 600°C lower. The same method can be employed also for the sole deposition of refractory boride/carbide coatings on C and SiC fiber preforms (Kütemeyer *et al.*, 2018, 2016; Zhang *et al.*, 2011; Zhu *et al.*, 2012). Zirconium is typically alloyed with lower melting metals such as copper or silver, to give alloys such as Zr₂Cu which significantly lower the operating temperature down to 1100°C or less. Dickerson *et al.* (2004) obtained a ZrC and W matrix via Zr₂Cu infiltration of a porous WC preform. Alternatively, the fiber preform can be infiltrated by other means, e.g., slurry infiltration, with different reactive powders such as B₂O₃ (Kütemeyer *et al.*, 2018), B₄C (Zhang *et al.*, 2011), or elemental boron (Kütemeyer *et al.*, 2016; Vinci *et al.*, 2020a) to give a ceramic matrix made of ZrB₂ and ZrC following reactions (1) and (2):

The liquid copper segregates on the surface of the sample, leaving a ZrC/ZrB₂ matrix with residual Zr₂Cu inside the pores. Other routes involve the use of transition metal-silicide alloys as infiltrating medium (Chen *et al.*, 2018; Maskaly and Chiang, 2008; Ye *et al.*, 2013) exploiting their reactivity towards carbon at reasonable processing temperatures (Phase Equilibria Diagrams Online Database NIST Standard Reference Database 31, 2019) like the example in reaction (3):

Recently, Zeng *et al.* (2017) have proposed the infiltration of C/C with Zr-Ti melt followed by pack cementation to obtain a matrix of Zr_{0.8}Ti_{0.2}C_{0.74}B_{0.26}. The material had a graded structure with a relative density of the matrix variable from 76% to 25%. The RMI method enabled the elimination of almost all porosity. In addition, large near-net shaped UHTCMC pieces can be obtained in a relatively fast process at low temperature. Compared to other infiltration techniques, such as PIP and CVI, RMI has the advantage of being very quick and cost effective. On the other hand, the melts, especially the ones containing transition metals, are very aggressive towards the fiber, and so a protective coating is often required. In addition, the final density of the component might be relatively high, close to that of a UHTC matrix, owing to residual metal alloy trapped in the matrix.

Preparation of UHTCMCs via Sintering Routes

Slurry Infiltration and Sintering (SIS)

Sintering is an essential step for ceramic consolidation, but it is rarely applied to fiber reinforced ceramic matrix composites (CMCs). This is because of (1) the need to apply pressure during sintering limits the component size and (2) the fact that the sintered component can contain degraded fibers and cracks formed due to intense residual stresses arising due to the Coefficient of Thermal Expansion (CTE) mismatch between matrix and fiber, with the fiber typically shrinking less than the matrix. For these reasons CMCs of C/SiC and SiC/SiC, are usually produced by the previously described technologies which are able to consolidate the material at lower temperature with lower matrix shrinkages (Heidenreich, 2014; Nannetti *et al.*, 2004). However, slurry infiltration and sintering (SIS) processes have been rethought for UHTCMC manufacturing. Once optimized the manufacturing procedure, in terms of slurry composition and rheological properties, impregnation methodology, and especially sintering schedule, SIS approach is highly attractive over the other non-sintering routes (Galizia *et al.*, 2018a; Zoli *et al.*, 2018; Zoli and Sciti, 2017). Impregnation of the fiber can occur by filament winding, where the yarn is dipped in a UHTC slurry (Silvestroni *et al.*, 2015b), or by direct immersion of the fabric into the UHTC slurry.

Hot pressing (HP) and spark plasma sintering (SPS) are well known consolidation techniques for bulk ceramics and largely used for UHTCs. The simultaneous application of high heating rates, mechanical pressure and high temperature (plus electrical current for SPS) allow the densification of even poorly sinterable materials, like borides and carbides (Córdoba *et al.*, 2013; Hu *et al.*, 2010a; Jin *et al.*, 2016; Lin *et al.*, 2015; Monteverde, 2007; Todde *et al.*, 2012; Xu *et al.*, 2012). Recently, it has been proved that these techniques can be successfully employed for UHTCMC manufacturing (Hu *et al.*, 2019; Lin *et al.*, 2015; Sciti *et al.*, 2015; Zoli *et al.*, 2020, 2017). However, it is important to mention that the sintering of fiber-reinforced composites, through HP or SPS, requires appropriate setting of the heating cycle in order to obtain a pore and crack-free matrix, preserve the fiber integrity and produce a suitable fiber/matrix interface. These features are in turn dictated by the type of fiber, ceramic matrix composition, fiber/ceramic volumetric ratio and have paramount importance in determining the thermo-mechanical properties of the final composite.

What are generally termed “SiC fibers” are not a pure SiC product, but rather nano-composites made of β -SiC nano-crystallites, turbostratic carbon and an amorphous SiCO phase (Berger, 2012). The presence of these latter two makes the fibers very reactive at high temperature, mainly involving carbon migration outwards and decomposition of the amorphous phase into SiC and SiO₂. Studies on the stability of commercial SiC fibers in UHTC matrices have allowed a thorough understanding of the fiber interaction with borides and carbides as a function of the sintering additive and temperature (Guicciardi *et al.*, 2010; Sciti *et al.*, 2014; Silvestroni *et al.*, 2015a,c, 2016b). SiC fibers reveal a multi-shell morphology upon sintering with an unreacted core, a region of coarsened SiC crystallites and Me-silico-carbides (where Me is the relevant cation of the boride matrix) and an outermost reaction zone of recrystallized SiC platelets, Fig. 1 (Silvestroni and Sciti, 2011). Because of the intrinsic unstable nature of SiC fibers, they behave locally as a sintering aid by reacting with borides and their residual oxides, favoring densification in the closest proximity, Fig. 1(b). Thus, the fiber/matrix interface is typically very strong and no bridging or pull-out during crack propagation can be observed for any matrices or sintering additives (Silvestroni *et al.*, 2010). Mitigation of the SiC fiber consumption can be obtained by use of external coatings, either pyrolytic carbon or Si-B-N-based ones. The application of any type of coatings has however a major weighting in the cost of the final composite.

The same delicate fiber processing has been assessed for all kinds of C fiber, both high strength ones deriving from polyacrylonitrile precursor (PAN-based) and ultra-high modulus deriving from pitch. In the first case, C fibers are obtained upon specific treatments below 2000°C and consist of a turbostratic crystalline structure, which is highly reactive in the sintering environment. In the second case, the fiber manufacturing process includes a heat treatment above 3000°C which results in a high degree of graphitization, which is considered to be more stable during sintering, even at 1900°C (Sciti *et al.*, 2020, 2015; Silvestroni *et al.*, 2016b; Zoli and Sciti, 2017). Nevertheless, in case of overfiring, even pitch-based C fibers may assume a jagged morphology with an important level of fiber degradation, opening and exfoliation, due to reactions with the surrounding ceramic phase, Fig. 2 (Guicciardi *et al.*, 2010; Huang and Young, 1995; Zoli *et al.*, 2017).

UHTCMCs with short fibers

Preliminary explorative studies on the fiber/UHTC interactions at various sintering temperatures and in the presence of different sintering agents started more than 10 years ago, at the Institute of Science and Technology of Ceramics, National Research Council of Italy (ISTEC-CNR) with the support of US AFRL funding. The object of that research activity was the production and characterization of ultra-high temperature ceramics possessing superior fracture toughness, i.e., containing different discontinuous reinforcing phases like SiC platelets, SiC whiskers or SiC/C short fibers. Specific studies coupling thorough microstructural analysis by transmission electron microscopy and mechanical characterization enabled to understand the sintering mechanisms and toughening phenomena occurring in these materials and progressively led to the identification of the critical processing parameters and toughness potential and limits of UHTC matrices reinforced with discontinuous phases (Sciti *et al.*, 2014; Silvestroni *et al.*, 2010).

UHTCMC with short fibers, i.e. starting length < 1 mm, can be readily realized by conventional ceramic technology, including ball milling, shaping and sintering. However, with the increase of the volume fraction of fiber, a homogeneous fiber dispersion is always more challenging to achieve, owing to the steric hindrance of the fibers. To date, up to 60 vol% fibers, with starting length of 300 μ m, can be incorporated in a UHTC slurry (Fig. 3). An increase of fiber amount results in an almost linear decrease of the

Fig. 1 (a)–(b) Morphology evolution of Hi-Nicalon SiC fiber in a ZrB_2 matrix illustrating the multi layered morphology and formation of different fiber/matrix interfaces after sintering at increasing temperature. final density (down to 84% for content of 50%), since the mass transfer and pore closure mechanisms are strongly obstructed by the fiber network, even under application of high mechanical pressures.

Increased matrix porosity resulting from increased fiber volume fraction has consequences also on the fiber/matrix interface. A more porous matrix will naturally develop weaker interfaces with any type of fiber as compared to a fully dense matrix where the fiber is well anchored in the ceramic phase, **Fig. 1(a)** and **(b)** and **Fig. 2**.

UHTCMCs with continuous fibers

The manufacturing of planar UHTC composites consists of the infiltration of SiC_f or C_f preforms with a UHTC-based slurry followed by their stacking to form a multi-layered green composite with a variety of configurations, e.g., uni-directionally oriented, with fabrics stacked in a $0/90^\circ$ configuration and also with more complex architecture of fiber preform, such as 2D and 2.5D, as shown in **Fig. 4**.

Research performed by [Levine et al. \(2002\)](#) led to a UHTC-based composite reinforced with 35 vol% fiber through filament winding using SiC_f (SCS-9) monofilament, slurry infiltration and hot pressing. However, it is only recently that multifilament SiC_f preforms have been successfully infiltrated by UHTC slurry and sintered. Two routes have been explored: in a first case, ([Silvestroni et al., 2015b](#)) Uni-Directional (UD) tapes of BN coated Hi-Nicalon SiC_f yarns, obtained by infiltration with a solvent-based ZrB_2 - ZrSi_2 slurry using a manual filament winding, were overlapped in a $0/90^\circ$ configuration and sintered by hot pressing at 1450°C . According to a second variation, ([Zoli et al., 2015](#)) UD Tyranno-SA3 SiC_f fabrics were infiltrated by an aqueous ZrB_2 - ZrSi_2 slurry, using a vacuum-bagging technique, stacked and subsequently hot pressed in the temperature range of 1450 – 1600°C . The use of a BN-coating for Hi-Nicalon fibers was effective in hindering fiber degradation during processing. However, regardless of the presence of coating or increased fiber volume fraction, the measured fracture toughness values were similar to monolithic ZrB_2 ceramics owing to an unfavorable $E_{\text{matrix}}/E_{\text{fiber}}$ ratio, which did not allow efficient load transfer from the brittle matrix to the high strength fibers. In addition, it was only when the BN-coating was present that a damage tolerant behavior was observed, whereas in the other cases a brittle fracture prevailed owing to the strong fiber/matrix interface.

Fig. 2 Effect of increasing sintering temperature on the morphology evolution and interface creation of pitch-derived C fibers immersed in a ZrB_2 matrix and sintered by HP. Examples of reacted (a) and over reacted interfaces (b).

Fig. 3 Examples of microstructure of hot pressed UHTCMC based on ZrB_2 and containing (top) increasing amount of Hi-Nicalon SiC fibers and (bottom) 50 vol% of C fiber viewed from cross section and top surface.

Combinations of carbon fibers and UHTC matrices result in more convenient composites from a flaw tolerance perspective. Also, for this class of composites the choice of fiber type, architecture and fiber/matrix composition ratio are of major importance, as they determine the sintering temperature and hence the fiber/matrix interface, degree of reaction and overall thermo-mechanical performance (Zoli and Sciti, 2017).

One main difference is related to the C_f source. Since PAN-based fibers are more sensitive to reaction with the matrix during sintering at high temperature, a strategy to limit such reaction and the following fiber degradation is the use of nano-sized ZrB_2 powders which allows a notable decrease of sintering temperature from above 1700°C to 1450°C (Zhang *et al.*, 2019). Alternatively, Zhang *et al.* proposed a brushing assisted infiltration followed by vacuum bagging, (Zhang *et al.*, 2019, 2018) and investigated the effect of pyrolytic coating (Zhang *et al.*, 2018) assessing its beneficial effect on the development of suitable fiber/matrix interface.

Generally, C_f are a better solution for strengthening and toughening ultra-high temperature ceramic matrices and for improving their thermal shock resistance, compared to SiC reinforcement (Song *et al.*, 2002; Vinci *et al.*, 2020b; Zoli *et al.*, 2018, 2015; Zoli and Sciti, 2017). On the other hand, C_f -reinforced UHTCs are more sensitive to oxidation than those reinforced with SiC_f (Sciti *et al.*, 2012).

Variations in UHTCMC Manufacture

Functionally Graded Composites

An intense and thorough investigation of UHTCMCs production and performance, either with short or continuous reinforcement and obtained through sintering or non-sintering methods, delineated the potential and limits of this new class of materials. One of

Fig. 4 Examples of UHTCMC composites obtained by SIS using cloths with different architecture of C fibers: unidirectional fabrics stacked in 0/0° configuration (UD), in 0°/90° configuration (0/90), plain clothes stacked with the same orientation (2D) and needle punched preform (2.5D).

the most relevant challenges, in view of the envisaged applications, is most certainly the resistance to highly oxidizing environments.

To benefit both from the ablation resistance properties typical of UHTCs and from a damage tolerant body containing a large fraction of fibers typical of CMCs, one research approach is to design a composite architecture which locally imparts each specific functionality. From what has been discussed above, in order to preserve the toughness in the bulk while improving oxidation performance, an accurate selection of dopants is a fundamental step to impart the desired properties. This can be achieved by modifying the liquid phase during sintering and thus the nature of the oxidation products upon exposure to high temperature environments.

The class of materials known as functional graded material (FGM) was first reported in the 90's for propulsion and airframe structural systems of astronautic flight vehicles to decrease thermal stresses arising during operation (Koizumi, 1993). These engineered materials are characterized by spatially varied microstructures created by a non-uniform distribution of the reinforcement phase with different properties, sizes and shapes, as well as by interchanging the role of reinforcement and matrix materials in a continuous manner. FGMs exhibit a gradual variation of material properties from one surface to the other and thus eliminate local stress concentration generally encountered in laminated multicomponent structures.

This concept has been recently validated in ZrB_2 matrices containing between 0 and 50 vol% of short SiC or C fibers (Silvestroni *et al.*, 2019a,b, 2016a) and with a gradual variation of the type or amount of sintering additive that enabled densification of the UHTC matrix, but limited reaction and degradation of the fibers, Fig. 5(a).

The mechanical properties of the developed FG UHTCMCs outperformed those of the analogous mono-reinforced composites, thanks to the exploitation of favorable residual stresses, achieving fracture toughnesses up to $10 \text{ MPa m}^{0.5}$ at 1500°C . This approach is particularly attractive as it enables a sort of UHTC coating to be obtained on a fiber-rich body in one single sintering step, avoiding problems of CTE mismatch and residual tensional states which could easily lead to spallation. While the processing is indeed that typical of ceramic processing, the obtained FG composites possess avant-garde aspects as compared to traditional CMCs in terms of both performance and cost.

Electrophoretic Deposition (EPD)

EPD has proved to be a facile method to create a thick UHTC coating of $5\text{--}50 \mu\text{m}$ onto C_f preforms (Failla *et al.*, 2019; Galizia *et al.*, 2018a). If EPD is implemented in the conventional SIS process, before the infiltration step, it allows the assembly of C_f into bundles coated with an UHTC coating that could have a different composition with respect to that of the matrix, Fig. 5(b). In this way, the degree of freedom in the design can be increased having the possibility to tailor the matrix composition and texturing. In

Fig. 5 Examples of UHTCMC obtained by (a) stacking of dry powder mixtures with increasing fiber content forming a FGM, (b) EPD of fiber fabric with a UHTC slurry subsequently infiltrated with a ZrB_2 slurry and sintered.

particular, the texturing in bundles allows to develop weak C/C and C/ ZrB_2 interfaces within the bundles, and this maximizes the overall structural properties (Galizia *et al.*, 2018a).

Mechanical Properties

At present, available mechanical data for UHTCMCs are still poorly reported and high temperature mechanical properties are even more difficult to find. As illustrated above there is plenty of reportage of different microstructural features, such as fiber volume fraction and dispersion, matrix density and composition, which often are not quantified in the published works even if they strongly affect the mechanical response of UHTCMCs. To further complicate a sound comparison of values, the available mechanical properties are measured with different testing approaches and specimen size.

For these reasons, in order to approach a direct comparison of differently processed UHTCMCs, it is preferable to set a test geometry and then compare the shape of load-displacement curves together with the analysis of failures. Fig. 6 shows load-displacement curves for different types of composites obtained by CVI, RMI, PIP and SIS. The experimental materials, still under development, presented here were realized in the framework of the C³HARME project (See “Relevant Websites Section”) and have all been tested using the same conditions and apparatus. Specimens prepared by CVI are reinforced with a 2.5D preform. Specimens prepared by RMI are reinforced with unidirectional (UD) fabrics stacked in a 0/0° configuration, while specimens prepared by PIP are reinforced with unidirectional fabrics stacked in a 0/90° configuration. Specimens manufactured by SIS are reinforced with UD fabrics stacked either in a 0/0° and 0/90° configurations. SEM images inset in Fig. 6 show the fracture surfaces (RMI and SIS) and side view (CVI and PIP) of failed specimens under flexural loading. All curves were obtained with the same test geometry: 4-point bending fixture with a lower span of 20 mm and an upper span of 10 mm; beams of 25 mm × 2.5 mm × 2 mm (length by width by thickness, respectively) and a crosshead speed of 1 mm min⁻¹.

The measured flexural strength of specimens obtained by CVI and containing about 25 vol% fiber with 2.5D architecture was 90 ± 30 MPa. The large scatter was due to the difference in fiber architectures of the specimen after machining. In fact, since bars have smaller dimensions with respect to the representative volumetric elements of fabric preform, tests gave high or low values depending on whether the outer surface under tensile stress had a prevalence of longitudinal (CVI, solid curve) or transverse fiber orientation (CVI, dashed curve), respectively (Galizia *et al.*, 2020). The RMI technique resulted in highly inhomogeneous samples with fiber-rich zones or mostly composed by the UHTC matrix. As a result, large scatter was observed with a maximum flexural strength of 720 MPa, typical of monolithic UHTCs (RMI, solid curve). On the other hand, zones with low fiber content and a dense matrix were typified by large flaws up to 500 μm and extremely low strength (RMI, dashed curve). In any case, catastrophic failure was recorded which suggested limited contribute of the fibers. Partial fiber consumption resulted in only around a 20 vol% fiber fraction after processing, explaining the poor performance. Specimens obtained by PIP and containing about 50 vol% fiber failed under inter-laminar shear. Hence, the actual strength of the composite was underestimated. For this class of composites, talking about inter-laminar shear strength is therefore more appropriate. By increasing the ZrB_2 content, the strength almost doubled, i.e. it increased from 5 MPa (PIP, dashed curve) to 11 MPa (PIP, solid curve).

Unidirectional carbon fiber-reinforced ZrB_2 composites realized by SIS with a FVC of 45 vol% and porosity around 6 vol% failed under a combination of inter-laminar shear and tensile stress. By changing the architecture from unidirectional to a 0/90° configuration the calculated maximum stress decreased from 255 ± 24 MPa (SIS, solid curve) to 150 ± 8 MPa (dashed curve),

Fig. 6 Typical load-displacement curves of UHTCMCs obtained through different manufacturing routes and fractured at room temperature in a 4-pt bending configuration with representative SEM images inset. Continuous or dashed lines refer to microstructural variation as labeled.

even if in both cases in the outmost surface the fibers were aligned parallel to the tensile stress. In the case of $0/90^\circ$ configuration, the calculated value should be corrected by taking into account the lower elastic modulus of the 90° layers (67 ± 2 GPa) with respect to that of 0° layers (206 ± 2 GPa), as follow:

$$\sigma_f = \frac{MtE_o}{\sum_n I_n E_n} \quad (4)$$

where M , E and I are the bending moment, Young's modulus and centroid moment of inertia of fiber layer in the outmost surface (o) among the n -layers (n), and t is the distance from the neutral axis to the outmost surface. However, Eq. (4) is not yet reliable owing to the failure of the 90° layers when tensile and compressive stresses within these layers exceed 61 ± 13 MPa and 172 ± 16 MPa, respectively. Their failure leads to the decrease of the effective elastic constant of damaged layers, as can be seen from the slope decreasing above 30 N of applied load. Furthermore, since broken 90° layers should offer different elastic constant if subjected to compressive or tensile stresses, the location of the neutral axis is not constant during the test and this should be taken into account in the t parameter. Owing to the difficulties in calculating the non-linear stress variation through the laminate thickness, the most reliable strength test is considered to be tensile testing. Currently, tensile strength data are scarce and limited to room temperature (Rubio *et al.*, 2019) and tensile strength testing is still challenging especially in case of matrix dominated CMCs. Comparison of different materials using the same test geometry enabled to identify the contribution of different microstructural parameters on the mechanical behavior of sintered UHTCMCs (Vinci *et al.*, 2020b).

For high temperature flexural strength and thermal shock, data available are even more limited although, for instance, first tests suggested that the 4-pt room temperature retained flexural strength of sintered UHTCMCs did not suffer the detrimental effects of thermal shock up to 1500°C (tests at higher temperatures are to date not available), and showed a gradual increase of flexural strength with increasing of temperature (Zoli *et al.*, 2018).

The characterization of fracture toughness is also very complicated, due to the lack of an accepted testing standard. Even if it is praxis to provide toughness values, not always the crack-stability criterion is investigated and the tests could not simultaneously

fulfill the plane-strain condition and limited crack tip plasticity (micro-cracking, de-bonding, etc.) (Inoue *et al.*, 2018). Anyway, sintered UHTCMCs seem to point out that interface coating is not a necessary condition to achieve high toughness in reinforced ceramic matrix composites upon manufacturing and processing conditions are carefully designed (Arai *et al.*, 2019).

Thermo-Ablative Performance

In order to validate UHTCMCs for hypersonic applications, the experimental set-up should simulate heat fluxes, gas compositions, surface pressures and flow velocities typical of an atmospheric re-entry. Only few facilities are able to reproduce these conditions. Hypersonic arc-jet wind tunnels are the most commonly employed besides oxyacetylene torch tests (Mungiguerra *et al.*, 2020, 2019, 2018; Paul *et al.*, 2013a; Savino *et al.*, 2018b). Although it is well known that the oxidation behavior of ultra-high-temperature ceramic materials and C-composites is crucial to their use, to date only limited data are available in reduced oxygen partial pressure environments and surface temperatures exceeding 2000°C, which are the most relevant conditions for the application of these materials as leading edges or nozzles.

The literature agrees on a general ablation behavior improvement when a traditional CMC is enriched with UHTC powder with the improvement having a strong dependence on the volume fraction, composition and compaction degree of the UHTC (Li *et al.*, 2013; Silvestroni *et al.*, 2019a,b; Tang *et al.*, 2009, 2007a).

A dedicated study on the effect of the secondary phases on the ablation behavior of ZrB₂ composites reinforced with 40 vol% C short fibers and containing 5 vol% SiC in combination with 5 vol% of silicide of various transition metals (MoSi₂, HfSi₂ or WSi₂) (Silvestroni *et al.*, 2019a,b) demonstrated that all composites successfully withstood extreme conditions in an oxyacetylene torch for 60s, but different responses were observed depending on the matrix composition which primarily impacted on the final density, typically between 83% and 94% of the theoretical value. The temperatures achieved on the surfaces of the samples tested also varied as a function of the residual porosity and ranged from 2080 to 2240°C. HfSi₂ additions offered the best performance and exceeded that of the baseline material that contained only SiC. It is believed that this was due to its ability to promote the elimination of porosity during densification and to the refractory nature of its oxide, HfO₂.

Many approaches have been investigated to implement the functionality of UHTCs into conventional CMCs. One approach is based on the protection of C/C composites with UHTC coatings (Corral and Loehman, 2008; Fu *et al.*, 2016; Haibo *et al.*, 2016; Liu *et al.*, 2013; Sun *et al.*, 2014; Zhou *et al.*, 2010). The main issue typically lies in achieving a good adhesion between the C/C composite and the UHTC phase due to the different chemistry of the materials and the thermal expansion mismatch that can cause the detachment of the coating under severe thermal stresses. (Corral and Loehman, 2008) have successfully achieved a good interface between the CMC and the coating by dip coating the C/C composite, previously heat treated at 1600°C for 4 h to induce graphitization on the surface, in a suspension of ZrB₂/SiC particles dispersed in a phenolic resin. Zhou *et al.* (2010) have obtained a homogeneous and dense coating of ZrB₂/SiC devoid of cracks via vapor silicon infiltration on C/C composites which showed good oxidation resistance up to 1500°C. Another way of implementing these properties is by embedding UHTC particles in the ceramic matrix of C/SiC composites. In this regard, Corral and Tang fabricated C/SiC composites with 4–18 vol% of ZrB₂ inclusions via CVI, and compared it to a C/SiC composite, showing how the former had increased oxidation resistance above 1000°C due to the synergy between B₂O₃ and SiO₂ forming a protective borosilicate scale with higher viscosity (Tang *et al.*, 2007b; Walker and Corral, 2014). Li and Zhang also reported the promising oxidation behavior of C/ZrB₂-SiC composites with high SiC content (Li *et al.*, 2009). In all these cases, the addition of relatively little amounts of UHTC phases significantly improved the oxidation and ablation resistances of CMCs. Therefore, more extensive studies were carried out on fiber reinforced UHTCs, where the UHTC phase was the main constituent, maintaining a non-brittle fracture behavior (Zoli *et al.*, 2018; Zoli and Sciti, 2017). Short-term oxidation tests were carried out on C/ZrB₂-SiC composites in order to evaluate the ability of the UHTC matrix to protect fibers from oxidation (Vinci *et al.*, 2018) and more in depth studies were carried out by TGA in order to assess the oxidation kinetics of carbon fiber reinforced ZrB₂/SiC composites up to 1500°C (Vinci *et al.*, 2017). Based on the promising results obtained

Fig. 7 Cross section SEM images of UHTCMCs containing (a) short or (b) continuous C fibers after exposure to high enthalpy flow above 2500°C with corresponding oxygen diffusion map. The image inset in (b) is an optical picture of the specimen after the test.

from these early studies, experiments moved to testing in relevant conditions. Short and continuous carbon fiber reinforced ZrB_2/SiC composites obtained by SIS were tested in a supersonic arc-jet wind tunnel and analyzed by SEM-EDS. Test specimens were exposed to supersonic plasma flow of simulated air at enthalpies up to 20 MJ kg^{-1} , surface heat fluxes of $1\text{--}5 \text{ MW m}^{-2}$ and stagnation-point pressure of 10 kPa. The maximum temperature measured on the surface of the sample exceeded 2500°C for 400s, the test specimens successfully survived the jet, as they appeared only whitened but still compact. SEM-EDS analysis carried out on the cross-section revealed the formation of a thin compact zirconia layer protecting the underlying pristine material (Mungiguerra *et al.*, 2020, 2019), Fig. 7.

Summary and Future Prospects

Ceramic matrix composites (CMCs) are replacing metals in different application fields thanks to the combination of good mechanical properties even at high temperatures, low deformation and high strength-to-weight ratios (Krenkel and Berndt, 2005). Ultra-high temperature ceramic matrix composites (UHTCMCs) are a new class of CMCs showing near-zero ablation/erosion above 2000°C specifically developed to replace C/C materials in rocket and hypersonic vehicle components such as nozzles, thermal protection system tiles or leading edges (Sciti *et al.*, 2018). The demand to extend the life of those components relates to the need to decrease the cost of space missions. The superior ablation/erosion resistance of components made of monolithic UHTCs has already been demonstrated in the past (Savino *et al.*, 2018a). However, their use in structural applications is limited by their low fracture toughness, low damage and thermal shock resistances. Currently, both non-sintering and sintering manufacturing routes are attracting increasing efforts to properly integrate UHTC matrices with reinforcing elements (Sciti *et al.*, 2018). Well-established non-sintering processes, CVI and PIP, allow the formation of a weak fiber/matrix interface, but the “non-sintered” UHTC matrix could suffer the ablation conditions (Paul *et al.*, 2013b). Owing to the lack of suitable UHTC organic/inorganic precursors in the market, another current strategy aims to enrich C/C or C/SiC with UHTC powders. RMI technology is a time saving technology compared to previous techniques, but fiber/matrix interface and residual metal content are difficult to control (Kütemeyer *et al.*, 2018). Powder slurry infiltration followed by pressure assisted sintering (SIS) is an alternative to non-sintering technologies. Densification of the ultra-refractory matrices through sintering at high temperature is the distinctive feature of this route, but it is also the most critical aspect of the process, because it may lead to embrittlement. SIS is time saving process compared to CVI and PIP and comparable to RMI, moreover it allows the control of fiber volume content and residual porosity through the modification of slurry rheology and sintering parameters, respectively (Sciti *et al.*, 2015; Zoli and Sciti, 2017).

At present, few available mechanical properties of fiber reinforced UHTCs are available, often parameters such as fiber type, volume fraction and dispersion, matrix density and composition are not shown in detail limiting the possibility to compare and correlate properties with microstructure. A race to define new testing standards for the mechanical properties of this subclass of CMCs is in progress. However, a first comparison among the samples realized by different manufacturing processes shows significant differences in mechanical behavior.

More demanding applications will continue to motivate both computational studies and experimental approach research on this field. Moreover, the entry of companies and industrial consortia in the funding sources is expected to accelerate the process toward the achievement of high Technology and Manufacturing Readiness Levels. Therefore, in the near future, efforts of researchers will focus not only on precursors synthesis, manufacturing process, microstructure/property relationships, but will also embrace the issues of real-world applications in extremely hot environments.

Acknowledgments

This work received support by the European Union’s Horizon 2020 research and innovation program under Grant Agreement no. 685594 (C³HARME: Next Generation Ceramic Composites for Harsh Combustion Environment and Space). The authors wish to thank N. Jain & DLR team (DLR, Stuttgart-Germany), J. Binner (University of Birmingham), A. Schoberth (CRT Airbus Group) for providing experimental materials for comparative mechanical testing.

Carbon-Matrix Composites

Composite Materials

A composite material (also known as a composite) is a material with two or more constituents that are artificially put together, so that a certain desired property is exhibited by the composite material, though it is not exhibited adequately by any of the constituents. Composite materials are to be distinguished from alloys. An alloy contains one or more phases, which form naturally, as dictated by the processing temperature, processing pressure and alloy composition.

One of the constituents in a composite is commonly the matrix, which is the constituent that binds the other constituent(s) together. The other constituents serve reinforcing or functional purposes and can be in various morphologies, such as fibers, particles, flakes, etc. The proportion of each constituent is best described by the fraction by volume (i.e., volume fraction) of each constituent. An example of a reinforcing constituent is one having modulus of elasticity considerably greater than that of the matrix, so that the elastic modulus of the composite is enhanced. An example of a functional constituent is one having thermal conductivity considerably higher than that of the matrix, so that the thermal conductivity of the composite is enhanced. For the thermal conductivity enhancement, it is important for the functional constituent to be at a volume fraction that is high enough for there to be a continuous thermal conduction path in the composite.

Composites are commonly classified according to the matrix material. Thus, there are polymer-matrix composites, cement-matrix composites (e.g., concrete), carbon-matrix composites, metal-matrix composites and ceramic-matrix composites. The type of matrix greatly affects the behavior of the composite. For example, the ability of the matrix to withstand high temperatures largely governs the ability of the overall composite to withstand high temperatures. The type of matrix also governs the composite fabrication method, which in turn largely governs the composite cost. Thus, cement-matrix and polymer-matrix composites are inexpensive compared to metal-matrix, carbon-matrix and ceramic-matrix composites.

Introduction to Carbon-Matrix Composites

Carbon-matrix composites refer to composites in which carbon is the matrix (Chung, 2017a). The carbon is solid carbon (essentially 100% carbon), which is to be distinguished from molecules that contain carbon atoms and other atoms.

There are three allotropes of carbon, namely graphite, diamond and fullerene. Graphite consists of sp^2 hybridized carbon atoms, with each carbon layer consisting of hexagonally arranged carbon atoms through a combination of covalent bonding and metallic bonding and the carbon layers in the AB stacking sequence (Fig. 1). Diamond consists of sp^3 hybridized carbon atoms, with each carbon atom being tetrahedrally coordinated through covalent bonding with four other carbon atoms. Fullerene consists of C_{60} molecules, with the carbon atoms in each molecule arranged to form hexagons and pentagons, as needed to form a sphere. The carbon nanotube is a hybrid of graphite and fullerene. Graphene is a single carbon layer, although the definition of graphene has been broadened to include carbon layer stacks consisting of up to 10 carbon layers. Graphene is a member of the graphite family.

Unless noted otherwise, the carbon matrix in carbon-matrix composites is in the graphite family, i.e., it consists of carbon layers, akin to graphite, but the three-dimensional crystal structure of graphite (Fig. 1) is not necessarily exhibited. Compared to the more commonly used polymer matrix, which provides polymer-matrix composites, the carbon matrix is attractive for its high temperature resistance, low coefficient of thermal expansion (CTE), high modulus of elasticity, high strength, high electrical conductivity and high thermal conductivity.

Reinforcement in Carbon-Matrix Composites

The reinforcing constituent in a carbon-matrix composite is most effectively continuous fibers (Chung, 2017b). The continuous fibers are in the form of tows (bundles), with thousands of fibers per tow. The designation 12K, for example, means 12,000 fibers in the tow. The tows are two-dimensionally or one-dimensionally arranged in each ply (i.e., each lamina). An example of a two-dimensional arrangement is one that involves the use of a fabric in the form of woven fibers. An example of a one-dimensional arrangement is one that involves all the fibers oriented in the same direction in the plane of the lamina. A typical composite (known as a laminate) consists of multiple laminae that are held together by the carbon matrix. Because the fibers are in the plane of the laminate, the laminate is much stronger in the plane of the laminate than in the through-thickness direction of the laminate. The interface between adjacent laminae in the laminate is known as the interlaminar interface, which has a substantial thickness (e.g., 10 μm) and is a matrix-rich region.

In order for all the fibers in each tow to contribute effectively to strengthening the composite, the carbon matrix must surround each fiber in each tow. If the carbon matrix surrounds each tow, without adequate filling of the small space between the adjacent

Fig. 1 The crystal structure of graphite.

fibers in a tow, porosity occurs within each tow of the composite and the fibers in the interior of each tow contribute little to strengthening the composite.

The most widely used continuous fiber in carbon-matrix composites is carbon fiber. The carbon fiber carbon-matrix composites (also known as carbon-carbon composites and abbreviated C/C) are the dominant high-temperature lightweight structural material. The continuous fibers can be woven or non-woven. The non-woven form is preferred for high-performance structures, since the fibers are anisotropic (with superior properties in the fiber axis than the transverse direction) and the slight local bending of the fibers in the woven form (Fig. 2) is not desirable for the most effective exploitation of the mechanical properties of the fibers.

In the C/C shown by the optical microscope photograph in Fig. 2, the carbon fibers are biaxially woven and manufactured by SGL Carbon, St. Marys, PA, U.S.A., with the product code SIGRABOND C/C. The carbon fibers are made from polyacrylonitrile (PAN), which is the most widely used polymer that serves as the precursor for carbon fibers. PAN fibers are converted to carbon fibers through a process known as carbonization (also known as pyrolysis).

At the same volume fraction, discontinuous (short) fibers are less effective as a reinforcement than continuous fibers, due to the imperfect bonding between the fibers and the matrix. Thus, at a fixed volume fraction, the strength and elastic modulus increase with increasing fiber length. Particles tend to be even less effective than discontinuous carbon fibers.

Carbon Matrix

The carbon matrix of the composite is in the graphite family. It can have various degrees of crystallinity. A low degree of crystallinity corresponds to turbostratic carbon, which is amorphous carbon with carbon layers that are not well-ordered relative to one another. In particular, in turbostratic carbon, the carbon layers are not perfectly parallel to one another, are not very flat, are limited in area, and are spaced farther apart than the layers in graphite (Fig. 1) (Chung 2019a). The higher is the degree of crystallinity, the more the structure approaches that of graphite. There is a gradation of structures among turbostratic carbons. For both turbostratic carbon and graphite, the in-plane bonding is a mixture of covalent bonding and metallic bonding, whereas the out-of-plane bonding involves van der Waals' forces. As a result, the materials are highly anisotropic, with the elastic modulus, electrical conductivity and thermal conductivity being much higher in the plane of the layers than in the out-of-plane direction.

A high degree of crystallinity of the carbon matrix is beneficial to the oxidation resistance, electrical conductivity, thermal conductivity, and elastic modulus, in addition to reducing the CTE. Because of the additional cost of high-temperature heat treatment that is needed to increase the degree of crystallinity, an increase in cost accompanies an increase in the degree of crystallinity.

The higher the degree of crystallinity, the smaller is the spacing between the carbon layers and the higher is the density. According to the manufacturer, the C/C shown in Fig. 2 exhibits a density of 1.5 g/cm^3 , which is considerably lower than the graphite density of 2.26 g/cm^3 . The low density of the C/C is primarily due to the low density of the carbon matrix.

A carbon fiber is in the graphite family, with the carbon layer (Fig. 1) preferentially oriented along the fiber axis. The degree of preferred orientation of the carbon layers in the carbon matrix tends to be lower than that in carbon fibers. This is partly because the tensile stress applied to the carbon fiber along the fiber axis during the fiber fabrication causes the carbon layers to align preferentially along the fiber axis. It is also because of the large aspect ratio of the fiber. A high degree of preferred orientation is

Fig. 2 Optical micrographs of a carbon-carbon composite with woven fibers. The vertical and horizontal scale bars are the same. The short scale bar has length 99 μm (0.0039 in.).

associated with anisotropy in the properties, including the mechanical, electrical and thermal properties. In particular, the thermal conductivity, electrical conductivity and elastic modulus are higher along the fiber axis than the transverse direction.

Fabrication of Carbon-Matrix Composites

Carbon-matrix composites are commonly made from the corresponding polymer-matrix composites by carbonizing the polymer matrix, which is called the carbon matrix precursor. An example of the carbon matrix precursor is pitch. The carbonization (also known as charring) is conducted at an elevated temperature (e.g., 1000–1500°C) in the absence of oxygen (Chung, 2017a). The char yield of the carbon matrix precursor refers to the yield of the carbon from the precursor through the carbonization process. Prior to the carbonization process, the polymer-matrix composite is commonly subjected to a low-temperature heat treatment (e.g., 200–350°C), which is for the purpose of oxidizing the polymer (changing the molecular structure), so that it does not melt during the heat treatment. This low-temperature heat treatment is known as stabilization (Chung, 2017a). The carbonization process also results in pores, which are detrimental to the mechanical properties. In order to reduce the porosity, the char yield of the carbon matrix precursor should be sufficiently high. In addition, impregnation of the precursor into the pores is conducted by infiltration under pressure, followed by carbonization. Multiple cycles of impregnation followed by carbonization are typically conducted in order to reduce the porosity adequately. This process of porosity reduction is known as densification. To further reduce the porosity, a vapor in the form of a carbonaceous gas (such as methane) is infiltrated into the composite under pressure, and then allowed to decompose under heat to become carbon. This process is known as chemical vapor infiltration (CVI), which is commonly used as the final step of densification, as conducted after the multiple cycles of impregnation and carbonization. In case that a high degree of crystallinity is desired, the carbonization is followed by graphitization, which is conducted at an even higher temperature (e.g., 2000–3000°C). Due to the complexity of the overall process of fabricating carbon-matrix composites, they are expensive compared to the corresponding polymer-matrix composites.

High-Temperature Resistance of Carbon-Matrix Composites

A polymer-matrix composite can withstand temperature up to around 300°C, with the temperature limit depending on the type of polymer. A polymer in the form of a thermoplastic polymer (such as a linear polymer) softens upon heating at the glass transition temperature and melts at the melting temperature, which is above the glass transition temperature. A polymer in the form of a thermoset (such as a network polymer) does not melt, but it decomposes.

In contrast to polymer-matrix composites, a carbon-matrix composite can withstand temperature up to around 2500°C, with the temperature limit increasing with increasing degree of crystallinity (degree of graphitization) of the carbon matrix. In order to obtain a high degree of graphitization, the temperature used to fabricate the carbon-matrix composite needs to be high (e.g., exceeding 2000°C for the purpose of graphitization), with the heating conducted in an inert atmosphere (e.g., argon, with nitrogen being not suitable, due to the reaction of carbon with nitrogen to form cyanide, which is poisonous), thus raising the cost of fabricating the composite. The high temperature resistance is important for numerous applications, such as resistance heating elements, aircraft brakes, re-entry space vehicles, missiles and missile launchers.

In the presence of oxygen (as that in air), carbon is oxidized at temperatures above about 700°C. The oxidation involves the conversion of carbon to vapor, thus causing the carbon to lose mass. The reactions can be the following (Chung, 2019a).

The mass loss means the formation of voids in addition to the reduction in the dimensions of the carbon-matrix composite. Both voids and dimensional reduction decrease the mechanical performance of the composite structure. This limited oxidation resistance greatly limits the high-temperature resistance of carbon-matrix composites, since the presence of at least a low concentration of oxygen commonly occurs in application environments.

In order to enhance the oxidation resistance of carbon-matrix composites, ceramic coatings (such as silicon carbide and silicon dioxide coatings) are often used. Ceramics are more resistant to oxidation than carbon, since they are already in the form of compounds. However, there is a temperature limit even for ceramics. For example, silicon carbide is oxidized and becomes silicon dioxide when the temperature exceeds about 1700°C and oxygen is present. The oxidation of the silicon carbide coating causes pores in the coating, thereby reducing the effectiveness of the coating for protecting the carbon-matrix composite from oxidation. The use of multiple coating layers is often used to provide the combination of coating-composite bonding and oxidation protection. There are approaches other than the use of coatings for enhancing the oxidation resistance of carbon. They include the addition of oxidation inhibitors, glass sealant and other substances to the carbon matrix.

The difference in the coefficient of thermal expansion (CTE) between the ceramic coating and the carbon matrix is another problem. The larger is the CTE mismatch, the greater is the thermal stress that is present upon heating and the greater is the tendency for the coating to debond from the carbon-matrix composite. A method to alleviate the CTE mismatch problem involves the use of a gradation of silicon concentration in the coating, with the silicon concentration being low in the part of the coating proximate to the carbon-matrix composite and relatively high in the part of the coating away from the carbon-matrix composite. In other words, the composition of the coating is not uniform at that of silicon carbide (SiC).

The CTE mismatch between the fiber and carbon matrix is a similar issue that degrades the high-temperature resistance. In addition, in the fabrication of the composite at a high temperature, cooling from the high fabrication temperature tends to cause debonding at the fiber-matrix interface if the CTE mismatch is significant. In order to reduce the CTE mismatch, the use of carbon fiber in conjunction with the carbon matrix is preferred. Thus, C/C is particularly common among carbon-matrix composites for high-temperature structural applications (Bevilacqua *et al.*, 2015; Chen, 2016; Chen *et al.*, 2013; Lu *et al.*, 2019; Nasibulin *et al.*, 2017; Raunija, 2015; Stepashkin *et al.*, 2015). Another reason for the dominance of carbon fibers over ceramic fibers (which also exhibit low CTE) is their combination of wide availability and low cost.

Refractory metals (metals with very high values of the melting point) such as tungsten and molybdenum exhibit low CTE, although the CTE is not as low as that of carbon. However, these refractory metals are heavy (with high values of the density), so that they are not suitable for lightweight structures.

Mechanical Behavior of Carbon-Matrix Composites

Carbon-matrix composites tend to be brittle compared to the corresponding polymer-matrix composites. The brittleness is not attractive for structural applications. Along with the brittleness are low toughness and low impact resistance. In order to circumvent the brittleness issue, the interface between the fiber and carbon matrix is designed so that the bond is not very strong. The interfacial weakness decreases for the strength and modulus of the composite, but it enhances the ductility and toughness. This enhancement is due to the deflection of the cracks as the cracks propagate and meet the fiber-matrix interface. Due to the weakness of the interface, the crack is deflected so that it propagates in the direction of the interface. The deflection causes the overall crack path to be tortuous. The tortuosity causes toughening, due to the energy consumed in crack propagation and the long length of the tortuous path.

According to the manufacturer, the C/C shown in Fig. 2 exhibits flexural strength 150 MPa, flexural modulus (comparable to the tensile modulus) 60 GPa, tensile strength 350 MPa, interlaminar shear strength 8 MPa, in-plane electrical resistivity at room temperature $2.4 \times 10^{-5} \Omega \text{ m}$, ash content 1000 ppm, and maximum application temperature 2000°C in vacuum or inert gas.

Multiscale Carbon-Matrix Composites

Multiscale composites (also known as hierarchical composites) involve constituents in different length scales. For example, a multiscale composite involves microscale continuous fibers, such as carbon fibers (typically of diameter about 7 Å), and nanoscale discontinuous filler, such as carbon nanotubes (typically of diameter less than 0.1 μm), all bound by a carbon matrix, such that the nanoscale filler is distributed in the carbon matrix (Chung, 2019a). Because the interlaminar interface is a matrix-rich region, the nanoscale filler tends to reside mainly in the interlaminar interface region.

The nanoscale filler results in a large area of the interface between the filler and the carbon matrix. Due to the very slight sliding at the interface during vibration (even in the elastic strain regime) and the friction associated with the sliding, the interface results in mechanical energy dissipation and hence enhancement of the vibration damping ability of the composite. This form of viscoelasticity is known as interface-derived viscoelasticity (Chung, 2019b), which is to be distinguished from the more well-known viscoelasticity that is based on bulk viscoelastic deformation (as the viscoelasticity in rubber).

Since the continuous fiber is the primary reinforcement that governs the strength and modulus of the composite, the volume fraction of the continuous fibers should be high (preferably at least 50%), whether the nanoscale discontinuous constituent is present or not. Thus, the volume fraction of the nanoscale constituent must be low. A low volume fraction cannot be achieved if the discontinuous constituent is not in the nanoscale, but, for example, in the microscale.

Another example of a nanoscale constituent is fumed alumina (Wang and Chung, 2016). Fumed alumina is much less expensive than carbon nanotubes. Alumina is a ceramic. Fumed alumina is in the form of porous aggregates of nanoparticles. Due to this morphology, fumed alumina is highly compressible (squishable), so that it can conform to the topography of the surface to which it is compressed. The conformability allows the fumed alumina to conform to the surface topography of the continuous fibers.

Instead of using a nanoscale discontinuous constituent in conjunction with a microscale continuous fiber to achieve a multiscale composite, one may grow a nanoscale constituent (such as carbon nanotubes) on the surface of the microscale continuous fiber (such as carbon fiber). The growth process involves chemical vapor deposition (CVD), using a carbonaceous gas (such as methane) as the carbon precursor. The CVD process is typically assisted by using a catalyst. A problem with this approach is that it is difficult for the carbon matrix to occupy the small space between the adjacent units of the nanoscale constituent (e.g., the small space between the carbon nanotubes grown on the carbon fiber). Another problem with this approach is that the continuous fiber with the grown nanoscale constituent is considerably more difficult to handle than the unmodified continuous fiber. The handleability is needed for the composite fabrication process. Yet another problem is that the thickness of the nanoscale constituent grown on a continuous fiber is substantial, thus causing reduction in the volume fraction of the continuous fiber in the composite. Since the continuous fiber is the primary reinforcement, a reduction in its volume fraction is detrimental to the strength and elastic modulus of the composite, even though the presence of the nanoscale constituent on the surface of the continuous fiber tends to increase the interlaminar shear strength of the composite. Still another problem is the high cost and limited batch volume for the nanoscale constituent growth.

Self-Monitoring

Due to the strategic nature of numerous applications of C/C, it is desirable to monitor (or sense) the stress, strain and damage in these materials. The monitoring of the stress or strain is pertinent to operation control, load monitoring and structural vibration control. The monitoring of the damage is pertinent to structural health monitoring and hazard mitigation. The monitoring can be achieved by measuring the electrical resistance (Wang and Chung, 1997; Xi and Chung, 2019, 2020a,b), the capacitance (Xi and Chung, 2019, 2020a) or the electric field (Xi and Chung, 2020b). The effect of stress/strain on the electrical resistivity (which relates to the resistance) constitutes a piezoresistive effect. The effect of stress/strain on the electric permittivity (which relates to the capacitance) constitutes stress-dependent dielectric behavior. The effect of the stress/strain on the electric field constitutes a piezoelectric effect. All three effects are stronger for C/C than carbon fiber polymer-matrix composite. Since this monitoring does not involve the use of any embedded or attached sensor, it is said to be self-monitoring (also known as structural self-monitoring). In other words, the structural material senses itself.

Self-Powering

Electric power is typically needed for structures. For example, power is needed for the operation of sensors and other devices that are associated with the structure. Self-powering refers to a structure serving as a power source. This is to be distinguished from the embedding of a power source in a structure.

An electret is a permanent (or quasi-permanent) electric dipole. Due to the fact that C/C is an electret and is electrically conductive, it is self-powering (Xi and Chung, 2020b). The electret is due to the interaction of a small fraction of the charge carriers with the atoms. The electret discharges upon short circuiting and charges upon open circuiting. The volumetric power density is much higher for C/C than carbon fiber polymer-matrix composite, due to the higher electrical conductivity of C/C. However, the power density is low, but the energy density is substantial.

Electromagnetic Shielding Effectiveness of Carbon-Matrix Composites

Due to the electrical conductivity of the carbon matrix and the non-conductivity of the typical polymer matrix, carbon-matrix composites tend to be more effective than the corresponding polymer-matrix composites in the electromagnetic interference (EMI) shielding effectiveness (Chung, 2001; Luo and Chung, 1999). EMI shielding is important due to the interference of radio wave and microwave with electronics. The shielding is needed for the electronics as well as the radiation sources. Related to EMI shielding is the shielding of the radiation resulting from the detonation of a nuclear bomb.

Thermal Conductivity of Carbon-Matrix Composites

Due to the thermal conductivity of the carbon matrix and the thermal non-conductivity of the typical polymer matrix, carbon-matrix composites tend to be more thermally conductive than their polymer-matrix composite counterparts. A high thermal conductivity helps to increase the thermal shock resistance. It also facilitates heat dissipation, which is needed for spacecraft, electronic enclosures, heat sinks, etc.

Introduction

The space industry has grown rapidly over recent decades, and this growth is expected to continue. This growth is stimulated in part by the development of low-cost reusable launcher technologies and the increasing use of commercial off-the-shelf (COTS) electronics (MacDonald and Badescu, 2014).

Ceramics are used in a broad range of space applications. These span from high strength high-temperature structural ceramics and Ceramic Matrix Composites (CMCs), ceramics for thermal protection systems, electronics, and wear components. The application areas range from propulsion system hardware for spacecraft, launcher and spacecraft structures, thermal protection systems, and substrates for space optics.

Ceramics have a range of properties such as chemical inertness, high service temperatures, low density, high hardness, and high wear resistance, that make them indispensable for a wide range of space applications. Ceramics can operate at a higher temperature, have reduced density compared to metals, and have higher specific strengths and specific stiffnesses. When metallic alloys in the hot sections of gas turbine engines are replaced by ceramic matrix composites, for example, a weight saving of around one third can be achieved (Misra, 2016). Lower density materials are particularly appealing for the space industry. Relative to advanced polymers and polymer composites, ceramics and ceramic composites are stable at significantly higher temperatures. Operation at higher temperature allows engine efficiencies to be improved, and in some cases enables the use of un-cooled design for components: this can simplify component design and reduce system weight. For structural applications, ceramics also have high specific strength and stiffness, and typically a low thermal expansion coefficient, which can enable designs with minimal thermal strains and give high dimensional stability. The environmental durability of ceramics in the atmosphere is also typically better than for metallic alloys, which can facilitate a longer component design lifetime.

The use of ceramics in space applications has increased steadily in recent decades. This increase is driven in part by a drive for weight reduction, which can lead to an increase in useable payload. Also, two further trends have contributed: the trend towards reusable launchers, and the increasing development of hypersonic spaceplanes and vehicles. Hypersonic vehicles, whether solely intended for atmospheric transit or orbital insertion, are exposed to very high heat fluxes over extended periods. Ceramics, which can operate at far higher temperatures than metals, appear to be an enabling technology for the development of these hypersonic vehicles. Ceramics and CMCs may, therefore, enable the technical feasibility of hypersonic vehicles as a cost-effective route to orbital insertion. Also, the increasing use of ceramics in space applications is driven, or enabled, by improvements in monolithic ceramic and CMC properties, as well as advances and cost reductions in fabrication technology, particularly for CMC reinforcement phases. However, it is still the case that ceramics have a high cost associated with design and fabrication, so a clear advantage must be evident before use is considered.

This chapter provides an overview of the uses of ceramics in their various forms in space applications. This includes a review of the “traditional” uses of ceramics, as well as consideration of emerging trends in ceramic and ceramic matrix composite (CMC) use where new advanced ceramics are replacing other materials such as metallic superalloys. Consideration is given to launchers, as well as satellites and manned spacecraft.

Design Considerations

Current trends within the space industry are toward an increasingly democratized and more commercial approach. Though scientific, navigation and military programs continue to be designed and managed by high-level governmental and intergovernmental agencies, much of the hardware and software development is industry-led. Areas of major change, however, are for smaller missions, now accessible to smaller companies and universities. These missions are often referred to as *New Space* (Sweeting, 2018).

With the miniaturization of both commercial and high-reliability electronics, it has become possible to utilize conventional launchers for *ride-share* missions. Coupled with the development of partially reusable launch vehicles, as well as smaller LEO-oriented launchers, the cost of launch has dramatically reduced in recent years.

It should be noted, however, that the miniaturization trend has not necessarily led to universal reductions in spacecraft mass. Conventional telecommunications spacecraft, such as those developed under the European ARTES framework (“Relevant Website section”), continue to grow in both mass and payload power while constellation-type spacecraft tend to decrease in both. Ceramic materials utilization will vary greatly between the two strategies.

The cost of the launch vehicle is a significant fraction of the launch cost, with propellant accounting for a relatively lesser fraction. Therefore, efforts have been made in the past decade to increase the lifetime of the launch vehicles. Achieving reusability

can necessitate the use of more durable materials in some key areas of launch vehicles, and this may be facilitated by the use of ceramics or ceramic matrix composites.

The use of ceramics in aerospace structural or thermo-structural applications is significantly impacted by their relatively brittle nature. Most ceramics are brittle and exhibit wide distributions of strength from component to component. They are sensitive to surface flaws and defects arising from impurities and variability in processing. This wide distribution of strengths requires the use of statistical processes such as Weibull analysis in the design of ceramic components to assess the likelihood of failure for a given loading condition. Research is ongoing to reduce this variability in the strength of ceramics. The use of reinforcement is effective in increasing the fracture toughness of ceramics. However, the inherently brittle nature of ceramics has undoubtedly limited the utilization of ceramics for applications where catastrophic failure must be avoided.

Much research in ceramics has focused on reducing the wide variability in strength exhibited by ceramics. This involves reducing how sensitive ceramics are to the presence of flaws and is countered by improving the material's fracture toughness. Some ceramics such as Si_3N_4 can be formed with "self-reinforcing microstructure", which results in improved fracture toughness (Pyzik and Beaman, 1993). Although optimizations of microstructure can deliver improvements for some ceramics, an alternative technique is possible; that is to use a reinforcement phase, forming a ceramic matrix composite. The reinforcement may be in the form of, for example, fibers, particles, or whiskers. For achieving the greatest improvement in fracture toughness and avoiding catastrophic failure, continuous fiber reinforcement is effective. Ceramic matrix composites with continuous fiber reinforcement are therefore attractive for highly stressed structural or thermo-structural applications. Although huge advances have been made in these materials, CMCs are not yet a mature material, and use of them in a critical space application entails some risk.

Future advances needed in CMCs include fibers that have good stability at high temperatures, improved environmental barrier coatings to protect from oxidation at high temperatures, and improvements in fiber-matrix inter-phases. Fabrication techniques, particularly for continuous fiber reinforcement are continuously improving. Further improvements in production techniques are needed to further reduce component cost. Technologies for joining mechanisms between ceramics and other materials would also benefit from improvement. In addition to this, improvements are needed in software tools for service life prediction of monolithic ceramic and CMC components (Devi and Rao, 1993).

The Space Environment

The space environment poses unique challenges for materials. Notable features of the space environment include vacuum, electrically neutral and charged particles (or plasma), radiation and micrometeoroids (Meseguer *et al.*, 2012). These effects are typically observed in combination rather than isolation and can cause a range of different issues covered in more detail below.

Vacuum stable materials are those that retain their functional properties in the absence of air and which do not outgas at pressures below 1×10^{-5} mbar. Outgassed matter can condense on cold surfaces and present a significant risk to optical hardware. Ceramics on their own typically present minimal-to-no outgassing risk, but care must be taken with composite materials where organic binders are used.

Ceramics possess greater stability under a Total Ionizing Dose (TID) relative to polymeric materials, owing to their inorganic composition. Ceramics are not immune from radiation effects, however, and care must be taken when ceramic materials are used on external spacecraft surfaces. Where thermo-optical properties are of critical importance, ceramics can be vulnerable to degradation under VUV/UV, low-energy particle irradiation, high temperature and low-energy x-rays.

Application Areas

The most extensive use of ceramics in spacecraft has been in the thermal protection system (TPS). Here, the material requirements are to withstand high temperatures and also the vibration and acoustic loading of re-entry. Ceramics have also been considered for use for structural applications in advanced future spacecraft, including hypersonic space-planes. The material most considered for these applications has been carbon-carbon (C/C) composites. Fiber-reinforced CMCs are also being considered for use and have superior oxidation resistance than C/C composite. In conventional space propulsion systems (liquid and solid propellant thrusters) there are many areas in which ceramics play an essential role. In emerging electric propulsion technologies, ceramics may be useful and they are already used on ion thrusters. Ceramics are also used for thermo-optical coatings, particularly solar reflector coatings. With the advent of 3D printing, the use of 3D printed ceramics for space applications has also been investigated in recent years for both exploration and settlement (Ghidini, 2018).

Ceramics are widely used in the manufacture of electronics. While the manufacture and use of ceramic chip capacitors and resistors are unlikely to change, the use of ceramics in electronic and RF applications is changing. A growing trend within space telecommunications is the move from analog to digital signal processing, meaning that fewer units are needed to operate in the RF domain, and that more of the hardware will make use of polymeric printed circuit boards (PCBs) rather than ceramic-based hybrids. The use of alumina and silicon carbide substrates commonly employed in RF and microwave electronic circuit board and heatsinks are not covered in this review. While some areas of ceramic use are decreasing, other applications are seeing significant growth such as Solid Oxide Fuel Cell (SOFC) and piezoelectric applications. The use of ceramics in SOFCs is advantageous due to their suitable electrical properties, thermal and structural properties and ability to operate at high temperature (Cable *et al.*, 2011; Ramadhani *et al.*, 2017). Piezoelectric ceramic materials (piezoceramics) such as barium titanate, lead zirconate titanate and

lead-free Perovskite ceramics are used as actuators and sensors are not covered here (Maillard *et al.*, 2009; Wu, 2020). Further detail on the use of ceramics in microwave applications is given by Varghese *et al.* (2020).

Thermal Management of Spacecraft

Atmospheric Re-Entry

A variety of thermal management techniques are used for components subject to high heating loads experienced during re-entry. The choice of a suitable TPS technique depends on the average heat load, peak heat load, duration of heat application, required mass of the vehicle, and requirements for re-usability. The duration of heat application has a significant impact on the choice of TPS technique. As well as re-entry in Earth's atmosphere, there is an increased focus on future Lunar and Martian missions. Approaches for TPS combinations for different re-entry requirements associated with Earth and entry for Lunar and Mars missions is given by Rasky *et al.* (2004).

The thermal management strategies may be classified as passive, semi-passive, and active cooling (Meseguer *et al.*, 2012). The passive thermal management strategies refer to the rejection of heat by radiation; semi-passive encompasses heat rejection by use of a phase change in some constituent of the thermal management system (e.g., ablative material or heat pipes), while active thermal management refers to the use of pumped fluid cooling.

Re-entry to the Earth's atmosphere and ultimately landing requires slowing down of a space vehicle from orbital velocity to landing speed. At high Mach numbers, heating effects of a body moving through a fluid become increasingly important. Aerothermodynamic analysis – the analysis of aerodynamic properties at several times the speed of sound—is an extension of aerodynamics to consider thermodynamic effects which become important at high Mach numbers (M). For hypersonic flow the Mach number or M is greater than or equal to 5. For re-entry to the Earth's atmosphere, Mach speeds in excess of $M = 25$ can be experienced. A substantial fraction of the orbital kinetic energy may be converted to heat upon re-entry, requiring the use of a thermal protection system. A summary and review of TPS's is given in more detail by Hurwitz (2010), while some further background and specific examples are discussed in this section.

Design of the thermal protection system for re-entry is a multidisciplinary problem, involving interactions between spacecraft shape, thermal protection material, re-entry flight path, structural mechanics, and flight mechanics (Ley *et al.*, 2009). The peak heat flux to the re-entry vehicle, and also the duration of flight along the re-entry trajectory will affect which cooling strategy is most appropriate. Re-entry trajectories may be classified as either ballistic re-entry trajectories (blunt re-entry capsules like Apollo capsule) and lifting re-entry trajectories (vehicles with lifting body characteristics like such as with a spaceplane like the Space Shuttle). The peak heat flux for a ballistic entry is extremely high, but occurs over a relatively short period of time, while for a lifting re-entry, the peak heat flux is significantly lower but is present for a longer period of time. The fraction of the total heat load absorbed depends on the ratio of skin friction coefficient to the overall drag coefficient of the re-entry vehicle. Blunt re-entry have low ratios of skin friction coefficient to pressure drag coefficient, which minimizes the heat load to the re-entry vehicle (Anderson, 1989; Ley *et al.*, 2009).

Additionally, the chemical composition of the re-entry vehicle's Thermal Protection System (TPS) surface can have a significant effect on the heat load to this same surface. In the bow shock region ahead of the re-entry vehicle, air molecules have a high vibrational energy and may dissociate into atomic oxygen and atomic nitrogen. Depending on the chemical composition of the TPS surface, recombination of dissociated oxygen and nitrogen atoms may occur resulting in the release of dissociation potential energy and thereby increasing the heat load. Surfaces with chemistries conducive to such recombination are termed *catalytic surfaces*, while those not conducive to such recombination are termed *noncatalytic surfaces* (Scott, 1992; Ley *et al.*, 2009). As a result of this, the material used for the TPS of a re-entry vehicle surface is preferably noncatalytic (Hirschel, 2015). Materials that behave in a noncatalytic manner include SiC ceramics and carbon/SiC composite (Ley *et al.*, 2009). SiC can be used to very high temperatures, as it has a sublimation temperature of $\cong 2900\text{K}$.

For space vehicles exposed to moderately high heat fluxes for short periods, a passive thermal insulation strategy may be appropriate and may be achieved using ceramics. The primary function of the TPS is to thermally insulate the structure from the external heat load, while passively cooling through thermal radiation, so that the structure can remain at a lower temperature (Glass, 2008). Radiative heat rejection is aided by the vehicle wall having a high thermal emittance at elevated temperatures. For SiC this is approximately 0.82 at 1000K, increasing to 0.98 at 2000K (Pidan *et al.*, 2005). An alternative strategy is to use the structure of the space vehicle as a heat sink. Rather than applying very thermally insulative materials, incident heat is conducted away from the vehicle surface and into the structure, raising its temperature, while a portion of the incident heat load will be rejected by radiation. This thermal management strategy was used for the X-15 space plane, which used an Inconel structure to allow operation at elevated temperatures (Glass, 2008).

In recent decades there has been strong interest in the development of air-breathing single-stage to orbit (SSTO) spacecraft. For such an SSTO hypersonic vehicle the heat flux during ascent is both high and of long duration (Glass, 2008). These factors have a strong impact on the choice of which thermal management system is most appropriate, and therefore the material choices. The mass of the thermal protection system is also a factor and may become a significant fraction of the total vehicle mass for very high heat flux re-entry vehicles (Ley *et al.*, 2009).

The various thermal management strategies that are used by different space vehicles are shown in Fig. 1 plotted as a function of temperature and exposure period. Re-entry capsules for Earth atmosphere re-entry all use ablative TPS designs as the heat flux is

Fig. 1 Various types of thermal management strategy used for different space vehicles plotted as a function of temperature and exposure time. From Glass, D.E., 2008. Ceramic matrix composite (CMC) thermal protection systems (TPS) and hot structures for hypersonic vehicles. Paper presented to Proceedings of the 15th AIAA Space Planes and Hypersonic Systems and Technologies Conference. Available at: <https://ntrs.nasa.gov/citations/20080017096>.

very high, but the exposure period is relatively short (Glass, 2008). For future space vehicles, hot structures may be utilized, or indeed required, for hypersonic vehicles, with the hot structure elements likely made from ceramics. These high temperature capable options are typically driven by a desire to save weight (Hurwitz, 2010).

Thermally insulative thermal protection materials

Several materials-mediated strategies are used for thermal protection of spacecraft and of course, the inherent thermal insulation and temperature stability of ceramics make them ideal for a range of applications whether that be extreme thermal isolation, such as with the Space Shuttle tiles or ablative applications.

The Space Shuttle orbiter is constructed from a traditional aluminum alloy skin-stringer design used for aircraft, and the structure must therefore be maintained at temperatures below 175°C (Glass, 2008). The thermal protection strategy is therefore that of an “insulated spaceplane”. The primary means of maintaining the airframe temperature to its allowable limit is the use of ceramic insulation tiles on the windward surface of the orbiter (Chapline *et al.*, 2010). On the leeward side, where heat fluxes are less extreme, blanket type insulation is used. The re-entry heat fluxes are highest on the nose-cap and wing leading edges, and for these regions reinforced carbon-carbon composite was used (Hurwitz, 2010).

When the Shuttle de-orbits and returns to earth, it enters the Earth’s atmosphere at an altitude of around 122 km and is traveling at around Mach 25. It uses friction with the air to slow down but this has the effect of heating the exterior to several thousand degrees. It is protected using some 24,300 tiles of two types: a black-coated High-Temperature Reusable Surface Insulation tile (HRSI) and a white-coated Low-Temperature Reusable Surface Insulation (LRSI). Both tile types are constructed from a lightweight composite material composed of silica fibers, alumina fibers and borosilicate glass that are fused using microwave processing. The black glass coating of HRSI tiles allows radiation of around 90% of the heat while the bulk of the tile absorbs the rest and they are used on the underside of the craft. The white LRSI tiles are coated with a “whitewash” of silica and alumina compounds and are used on parts of the upper fuselage.

NASA’s Orion crew capsule will similarly use the same insulative material from the Space Shuttle with 970 tiles on its back shell panels to protect the capsule structure during re-entry, as illustrated in Fig. 2. The Orion capsule is designed for re-entry at higher speeds than the Space Shuttle to facilitate re-entry from Mars transit and speeds are expected to be up to 32,000 km/h. Temperatures experienced by the tiles during re-entry are predicted to reach 1700°C. Due to the fragile nature of this material, it is vulnerable to damage from micrometeoroid impact, which could have a deleterious impact on the effectiveness of the TPS. Further detail is given by Harris *et al.* (2018).

The new ESA Intermediate eXperimental Vehicle (IXV) is a demonstrator re-entry craft that has been developed to test atmospheric re-entry approaches and perform in-flight experiments to verify and validate new systems and approaches (Tumino *et al.*, 2016). It combines ablative (Cioeta *et al.*, 2016) and non-ablative approaches (Buffenoir *et al.*, 2016) in the form of P50 cork and Carbon-Silicon Carbide CMCs respectively.

NASA’s Parker Solar Probe (PSP), which will become the closest spacecraft to approach the Sun will approach within 9.9 solar radii at perihelion, where it will experience an incident heat flux of 70 W cm⁻² (Dantzler *et al.*, 2008). The main heat shield of PSP is composed of a sandwich panel of C/C face-sheets that surround a thick layer of thermally insulative carbon foam, illustrated in Fig. 3. The carbon foam layer, which is around 15 cm thick, provides substantial thermal insulation and reduces the heat load to the spacecraft bus to around 0.001% of the incident heat flux from the Sun. C/C was chosen for the face-sheets due to its

Fig. 2 Black colored thermal protection tiles installed on the back shell of NASA's Orion crew capsule during assembly as Kennedy Space Center, Florida, USA. Image from NASA.

Fig. 3 Section of C/C sandwich panel as used for Parker Space Probe. Image from NASA Goddard.

combination of high specific strength, low outgassing, and ability to operate at the extreme temperatures encountered (Dantzler *et al.*, 2008).

Non-ablative thermal protection materials

Non-ablative thermal protection materials use re-radiation to reject heat back to the atmosphere. These non-ablative thermal protection materials are typically special ceramics, but refractory metals such as rhenium or tungsten may be used in some applications.

Carbon can be used up to very high temperatures in a vacuum (sublimates at very high temperatures). However, carbon would burn during re-entry to the Earth's atmosphere which contains oxygen (Ley *et al.*, 2009). For a re-entry vehicle with the geometric configuration of the Space Shuttle Orbiter, the bow shock has the highest strength, and the temperature increase across the shock is highest, in the nose-cone region (Ley *et al.*, 2009). This is the stagnation point region of the nose. For the Space Shuttle, carbon/carbon composite was used for the nosecone. Applications have also been found for C/C and C/SiC in the Hermes spaceplane, Fig. 4.

Glass (2008) notes that the primary factors/challenges that affect the implementation of CMC materials for hot structures are the environmental durability against dissociated oxygen and nitrogen during re-entry and also the fabrication challenges. Use of ceramics in load bearing structural applications for space have a higher barrier to implementation than non-load bearing applications (Levine and Herbell, 1991). For load-bearing (structural) applications the reliability of the structural component, which is strongly linked to the fracture toughness of the material, becomes of great concern. Reliability may be enhanced by the use of fiber reinforcement to increase fracture toughness; i.e., to form a CMC. Other factors also hinder the implementation of

Fig. 4 Overview of materials uses proposed for the thermal protection system of the Hermes spaceplane. From Christin, F.A., 2005. A global approach to fiber nD architectures and self-sealing matrices: From research to production. *International Journal of Applied Ceramic Technology* 2, 97–104.

ceramic or CMCs in load-bearing applications, including challenges in design, development of appropriate design methodologies for these materials, quantitative assessment of reliability and life predictions, joining mechanisms to other hardware, and the high cost of design and fabrication. Advancements in temperature capabilities of fibers are also sought, while toughening mechanisms of matrices, through the use of all-oxide continuous fiber-reinforced CMCs for high temperature structural applications are also under development (Simon, 2005).

Ceramic Thermal Control Coatings for Satellites

The surface of a spacecraft is exposed to widely varying thermal environments over the course of an orbit. Without carefully designed surface thermo-optical properties, such spacecraft would undergo large fluctuations in temperature. In particular, surfaces exposed directly to the Sun's thermal radiation, which is equivalent to approximately 1350 W m^{-2} , would quickly lead to overheating. For satellites, such overheating could lead to failure of electronics, batteries, or other critical hardware, while for crewed spacecraft, over-heating could be hazardous.

In addition to thermal radiation, the surfaces of spacecraft are also exposed to a wide range of non-thermal solar and cosmic radiation. The non-thermal forms of solar radiation include gamma-rays, X-rays, and short wavelength UV radiation in addition to proton and electron fluences, while cosmic radiation includes contributions from gamma-rays, X-rays, and UV radiation. In low earth orbit, spacecraft are also exposed to non-trivial concentrations of atomic oxygen. The outer surfaces of the spacecraft are exposed directly to these various forms of high energy radiation, and these can have damaging effects on thermo-optical coatings. Interaction of charged particles with the thermo-optical coating can also lead to surface charging if the coating is not electrically dissipative or conductive. For this reason, a spacecraft coating needs to serve not only the role of thermal control but also potential control (i.e., electrical potential) (Marco and Remaury, 2004).

The thermal protection system (TPS) of spacecraft typically include a range of different technologies, including multi-layer insulation blankets (MLI), highly reflective optical solar reflector (OSR) panels, and diffusely reflecting or absorbing thermo-optical coatings. Each different technology has its advantages and disadvantages. Ceramic solar reflector coatings are one of the most important solar reflector technologies. These coatings are diffusely reflective, and therefore avoid problems of glint reflections impinging on other parts of the spacecraft. They are lower in mass per unit area than OSRs. In addition, they can be applied conformally to complex geometries, while OSRs are limited to rigid, flat panels (Sun *et al.*, 2018).

Thermal-control coatings passively regulate spacecraft surface temperatures through manipulation of thermo-optical material constants, specifically solar absorptance α_s and infrared emittance ϵ . A simplification of an equation, derived from a combination of the Stefan-Boltzmann law and the first law of thermodynamics (applied to a uniform isotropic sphere), may be used to predict equilibrium surface temperatures of thermal-control surfaces (Doherty *et al.*, 2016). The equilibrium temperature of a spherical body or surface at

normal orientation to some radiation source (T_{sc}) is proportional to the ratio of the normal solar absorptance of the surface (α_s) and the normal emittance of the thermal control surface (ϵ_N) i.e., T_{sc} is proportional to α_s/ϵ_N . The effect of this ratio are summarized in Fig. 5. Lines are shown corresponding to various different values of the α_s/ϵ ratio, along with corresponding equilibrium spacecraft temperatures (T_{sc}) that would occur for a coated isothermal sphere at 1 AU from the Sun (Meseguer *et al.*, 2012).

A number of recent craft will experience extreme thermal and radiative environments. Two spacecraft that will transit very close to the Sun include the European Space Agency's Solar Orbiter (SolO), and the Parker Solar Probe (formerly Solar Probe Plus). The European Space Agency mission, Bepi Colombo, will experience extreme heat and radiation as it makes its journey to Mercury.

Solar reflector (white) coatings are used to minimize the equilibrium temperature of spacecraft surfaces by minimizing absorptivity in the visible and near-infrared range of 0.25–2.5 μm , while maximizing absorption in the middle- to far-infrared spectrum of 3–30 μm (which we refer to as infrared emissivity). This is of greatest importance for radiator panels, which need to reject excess heat from electronics and instrument to space. Any heat absorbed from the space environment must additionally be rejected, which leads to an increase in required radiator mass. These coatings are commonly in the form of a paint, often based on alkali metal-silicates, dimethyl-silicones, or polyurethane binders, with a pigment phase, which is often ZnO (Henninger, 1984). Examples include Z-93P (IITRI, now Alion, USA), AZ-93 (AZ Tech, USA), SG121FD (MAP, France), Nanovation V14 (CeraNovis, Germany), SolarWhite (ENBIO, Ireland).

Completely inorganic coatings such as SolarWhite (Doherty *et al.*, 2016), used on Solar Orbiter, and Nanovation (Holynska *et al.*, 2019), used on Bepi Colombo, are ideally suited to the space environment where degradation of organic bonds can result in an increase in absorptance over time. An alternative treatment to applied surface coatings is the use of Plasma Electrolytic Oxidation (PEO) to grow an oxide layer on a metallic surface (Simchen *et al.*, 2020). However, these treatments, as well as those utilizing polymeric binders with oxide pigments, can be susceptible to moisture and organic pick up during normal assembly activities, as well as storage.

If the absorptance cannot be guaranteed due to mission environmental conditions, a stable, black thermo-optical surface can be preferred. While this comes at a temperature cost, this approach minimizes changes in the thermal management of the craft over its mission life and can simplify the overall system. Flat absorber (black) coatings can be used on the inside or outside of spacecraft, in order to promote radiative heat transfer, and thereby isothermalize the hardware. These typically have an α_s/ϵ_N ratio of 1, as illustrated in Fig. 5. They are used on the outside of spacecraft in some specialized applications, an example being high-temperature MLI to minimize stray light reflections. The Solar Orbiter mission utilizes a black, flat absorber, calcium phosphate ceramic coating, SolarBlack. This extremely thin ($\approx 5 \mu\text{m}$), surface coating has no binder phase to degrade at elevated temperatures, and does not impact the conductivity of the surface at high, or low temperatures (Doherty *et al.*, 2015). SolarWhite and SolarBlack thermal control coatings used on the Solar Orbiter are illustrated in Fig. 6.

The Parker Space Probe (PSP) was launched on 12th August 2018 and will explore the Sun's corona. It will transit closer to the Sun than any previous spacecraft. The Sun-facing heat shield will reach temperatures of around 1400°C at perihelion (Dantzler *et al.*, 2008). The heat-shield of PSP has a solar reflector coating on the Sun-facing surface, which is an aluminum oxide coating approximately 100–125 μm in thickness, which is applied by plasma spray process by Plasma Processes, Inc., (Huntsville, Alabama, USA). This is applied to a C/C composite substrate to reflect a large portion of the incident UV and improve the passive cooling through thermal emittance, illustrated in Fig. 7.

Fig. 5 Solar absorptance (α_s) vs. hemispherical total emittance (ϵ). Regions are denoted as solar absorbers (SA), flat absorbers (FA), solar reflectors (SR), and flat reflectors (FR). Space Propulsion Applications

Rocket Engine Components

As with the design of many other components and systems for space applications, a lighter Solid Rocket Motor (SRM) or Liquid Rocket Engine (LRE) allows more payload to be lifted into orbit, which reduces the cost to orbit per unit mass of payload. In LREs, ceramics are considered for thrust chambers, exit cone sections, and a variety of turbopump components including turbine blades, valves, bearings, and other hot-section components.

Solid rocket motor (SRM) nozzles

There are several different parts of a solid rocket motor (SRM). The components involved in generating thrust are the nozzle throat (the narrowest part, where the Mach number becomes 1), and the nozzle exit cone. The nozzle throat has to withstand very high temperatures of $> 3000\text{K}$, very high heat fluxes and thermal gradients. The throat section is also exposed to physical and chemical erosion processes from the hot propellant. This places extreme requirements on the material used for the nozzle throat. The carbonaceous materials graphite and carbon/carbon composites are attractive for this application as they have a significantly lower density ($\rho \cong 2.2 \text{ g cm}^{-3}$) than refractory metals such as niobium ($\rho \cong 8.57 \text{ g cm}^{-3}$) and tungsten ($\rho \cong 19.3 \text{ g cm}^{-3}$). Relative to refractory metals, graphite and carbon/carbon composites additionally have high thermal conductivity. The properties of graphite and carbon/carbon composites therefore make them attractive candidate materials for the throat sections of SRMs. While graphite is a brittle material, carbon/carbon composites have improved tensile properties at elevated temperatures (see Fig. 8) and have become the *de facto* material choice for the throat section of SRM nozzles (Christin, 2008).

Carbon/carbon composites may be constructed based on different geometries of carbon fiber arrangements, either two-dimensional or three-dimensional in nature. Those based on two-dimensional fiber arrangements consist of preforms made from cloth-type fabrics. These are simpler and lower in cost to construct, have a greater tendency for inter-laminar cracking, and are generally limited to thin components. Carbon/carbon composite using two-dimensional preforms are used for example for solid rocket motor cones for some apogee kick motors (Christin, 2008). Three-dimensional reinforced preforms are produced by interweaving, which results in improved delamination resistance and improved isotropy.

For many aerospace applications, high specific strength is required at high temperature. Specific strength is plotted as a function of temperature for several classes of materials in Fig. 9. Ceramics and CMCs have typically lower density than metals, coupled with high strength, which gives them high specific strengths. As shown in Fig. 9, many metals and metallic alloys, including Ti and Inconel, and MMCs have excellent specific strength at room temperature. However, their strength decreases at moderately high temperatures. In contrast, ceramics and CMCs retain their strength to higher temperatures.

Liquid rocket engines (LRE)

Liquid rocket engines (LRE) are comparatively more complex in design than SRMs. They are composed primarily of turbomachinery for pumping of fuel and oxidizer, an injector plate to atomize and mix the propellants, a combustion chamber, and a converging-diverging De Laval nozzle. The combustion chamber and sections of the C-D nozzle from the converging section, nozzle throat, and initial part of the diverging section are the regions of the LRE where the highest heat fluxes occur. The temperatures in these regions may exceed 3300°C in the combustion chamber and $1600\text{--}2700^\circ\text{C}$ in the nozzle section and so are too high for any conventional materials. Therefore, these sections are commonly manufactured as a single unit from a metal such as a copper alloy, with regenerative cooling used to cool these components. The primary material properties required are high thermal conductivity and high strength. The metals used in the combustion chamber and initial section, whether copper or nickel-based superalloys, have a high density (circa $8\text{--}9 \text{ g cm}^{-3}$) and therefore the construction of the whole LRE from these materials would result in a very heavy engine. Therefore, it is desirable to replace metallic components of an LRE, where possible, with high specific strength ceramic components. The primary components considered for replacement by ceramics are the nozzle

Fig. 9 Specific strength of several material classes as a function of temperature. Adapted from Glass, D.E., 2008. Ceramic matrix composite (CMC) thermal protection systems (TPS) and hot structures for hypersonic vehicles. Paper presented to Proceedings of the 15th AIAA Space Planes and Hypersonic Systems and Technologies Conference. Available at: <https://ntrs.nasa.gov/citations/20080017096>.

extensions, particularly for upper stages, while some investigations of ceramic combustion chambers have also been investigated (Misra, 2016).

A portion of the diverging section of the nozzle, out to an expansion ratio of around 5–8 is typically incorporated into this integrated assembly, and the expanding portion of the nozzle downstream of this is then typically constructed from a different material with use of a different cooling strategy (Ley *et al.*, 2009). This is called a *nozzle extension*. The cooling strategies used for this downstream section of nozzle include regenerative cooling, dump cooling, film cooling, transpiration cooling, and radiative cooling. Metals rather than ceramics have typically been used for the combustion chamber and throat section due to the need to integrate cooling channels for regenerative cooling, and the requirement for thin-walled material of high thermal conductivity to ensure efficient heat transfer from the hot gas to the propellant in the channels, and metals are better suited for this.

Advantages of replacing a metallic nozzle extension with a ceramic one include a reduction in mass (which allows payload mass to be increased), and higher temperature capabilities than metals. In addition, with a ceramic nozzle extension, a simpler cooling strategy may be used which simplifies design and can further reduce mass. Material requirements for use of ceramics in a nozzle extension are quite restrictive. The material must operate at very high temperatures of circa 1700°C, must be chemically resistant, have high thermal shock resistance, have low density, and also be tolerant to damage (Misra, 2016).

Liquid rocket engines have typically utilized either refractory metals or highly thermally conductive metals in combination with some form of propellant cooling. Christin notes that carbon/carbon composites began to be used in some LRE designs from the mid-1990s (Christin, 2008). The primary ceramic materials that are suitable for use in nozzle extensions are C/C composite, SiC/SiC composite, and C/SiC composite (carbon fiber reinforced silicon carbide). SiC/SiC is produced, for example, by Snecma Propulsion Solide, France. SiC/SiC composites may be produced by the chemical vapor infiltration (CVI) method of infiltration of a preform, liquid impregnation and pyrolysis, or a combination of these techniques (Christin, 2008). The CVI infiltration method yields a pure SiC matrix, and results in superior thermal stability than the liquid infiltration method (Christin, 2008). The CVI infiltration method is performed by cracking of methyltrichlorosilane gas to infiltrate a preform at high temperature (Christin, 2008).

SiC/SiC composites exhibit good room temperature strength and are stable up to very high temperatures. SiC/SiC additionally has very good high-temperature strength and specific strength. SiC/SiC has higher fracture toughness than monolithic SiC. These materials have suitable properties for use in the thermal protection systems of re-entry vehicles (Christin, 2008).

One technique for producing SiC/SiC CMCs is the construction of a prepreg, followed by melt infiltration. SiC fibers are first pre-treated with interface layers, which may include boron nitride and silicon carbide (Misra, 2016). The fibers are then formed into a prepreg, held together by a polymer binder incorporating SiC particles. The composite is then heated to high temperature, which decomposes the polymeric binder. Liquid silicon is then infiltrated into the material. This results in a reaction between the silicon and carbon in the prepreg and thereby forms the SiC matrix in situ (Misra, 2016).

A notable example of the use of carbon/carbon composite for a liquid rocket engine is the use for the Pratt & Whitney RL10B-2 liquid rocket engine. This is a cryogenic propellant upper stage LRE. The rocket stage operates at high altitude near-vacuum conditions and therefore requires a high expansion ratio nozzle. A monolithic high expansion ratio nozzle would be very long, which would add to the overall size and mass of the launcher. As a result, the nozzle incorporates a nozzle extension, which allows compact packaging of the LRE inside the launcher, and then extends into position for use (see Fig. 10). The RL10B-2 has been successfully used for the Delta 3 upper stage and the EEC is made from carbon/carbon composite weighing only 92 kg; it is produced by Snecma Propulsion Solide, France (Christin, 2008). This is made from Novoltex[®] C/C composite.

For liquid propellant rocket engines, the thermo-mechanical properties of carbon/ceramic and ceramic/ceramic composites make them well suited for use in exit cones. These materials can be used, for example, in place of metallic cone structure with ablative liner (Christin, 2008). The high allowable use temperature of these materials enables the use of propellant cooling

Fig. 10 Pratt & Whitney RL10B-2 liquid rocket engine, incorporating Snecma carbon/carbon nozzle extension. From Christin, F.A., 2008. CMC materials for space and aeronautical applications. In: Krenkel, W. (Ed.), *Ceramic Matrix Composites: Fiber Reinforced Ceramics and Their Applications*. Weinheim: Wiley-VCH Verlag GmbH. pp. 327–351.

techniques in the exit cone (such as film cooling or dump cooling) to be avoided and can thereby result in increased rocket performance and simultaneously decreasing design complexity (Christin, 2008).

Christin (2008) notes that for liquid propellant rocket engines, the nozzle exit cone may be exposed to very hot oxidative combustion gases i.e., this is in contrast to SRMs, where combustion occurs at the propellant grain surface, which on average is more distant from the nozzle. As a result of this, for LREs to use non-cooled high-temperature ceramics, ceramic materials with suitably high oxidation resistance (i.e., superior to that of C/C composite) are required (Christin, 2008). These can include coated C/C composite or other ceramic composites.

Transpiration cooling, mentioned in the previous section for structural applications, for use in LREs involves effusion/injection of one of the propellant components (fuel or oxidizer) through a porous combustion chamber wall into the combustion chamber to achieve cooling in the near-wall region. For this application, sintered metals may be used; however, these can be limited by their maximum operating temperatures and the need to increase the wall thickness to achieve the required structural strength with the porous material (Ley *et al.*, 2009). As an alternative to sintered metals, porous fiber-reinforced CMC may be used as a wall material for transpiration cooling (Ley *et al.*, 2009). CMCs have typically higher maximum operating temperatures than metals, while also having lower density and higher specific strength, which can allow the component mass to be reduced (Ley *et al.*, 2009). In addition, the higher operating temperatures allowed by CMCs would reduce the required flow rate of coolant (Ley *et al.*, 2009).

Misra (2016) notes that one of the systems developed was a hybrid metallic-ceramic design, which incorporated metal tubes into a C/SiC composite structure, with the metal tubes carrying the coolant. In addition, all-ceramic designs have also been developed, and these have the advantage of the potential for lower mass (Misra, 2016). One actively cooled CMC nozzle section demonstrator was developed by Rockwell Scientific Company and tested at NASA Glenn Research Center (Marshall and Cox, 2008). Rather than being constructed from individual tubes that were joined together, this was constructed by weaving the carbon fibers into an integrated tube-wall assembly as a single component. Further flight applications are given by Böhrk (2017). Additionally, there is growing interest in ceramic use in catalyst beds for smaller, monopropellant thrusters, widely used for attitude control thrusters. Hydrazine monopropellant thrusters typically use iridium or cobalt catalyst, which is dispersed onto a bed of porous alumina pellets of diameter 1.5–3 mm (Sutton and Biblarz, 2001) but new additively manufactured alumina structures with feature sizes of 0.15–0.3 mm can be fabricated and have demonstrated equivalence to existing solutions (Essa *et al.*, 2017).

Electric Propulsion

Electric propulsion thrusters use ionizable gases as a means to create accelerated matter and thrust. While electric propulsion thrusters are capable of generating ion speeds far in excess of chemical reactions, the resulting thrust is much lower. These systems are used for attitude control (Ley *et al.*, 2009), as well as being the main propulsion to achieve a high change in velocity, Δv , (e.g., Deep Space 1, Hayabusa, SMART-1, BepiColombo) for interplanetary missions (MacDonald and Badescu, 2014).

The use of ceramic materials in electric propulsion is outlined for two examples below: Ion thruster and the Variable Specific-Impulse Magneto-Plasma (VASIMR) rocket engine. Further details can be found in [Goebel and Katz \(2008\)](#) and the review paper by [Holste et al. \(2020\)](#).

Ion and hall thrusters

Mentioned previously, as the life of a satellite is extended, the use of electric propulsion is subject to the same requirements of reliability, robustness, electromagnetic compatibility (EMC), radiation hardness, non-hazardous interaction with the satellite, and energy efficiency ([Holste et al., 2020](#)). The use of ceramic materials in critical areas of the propulsion systems enables this. Ceramics provide electrical conductivity and erosion stability in the plasma chamber and accelerator grids. Both Ion and Hall thrusters utilize plasma generation to ionize the propellant gas, offering advantages in efficiency and thrust generated respectively ([Goebel and Katz, 2008](#)).

Orbit control thrusters generate low thrust (>0.001 mN) while main propulsion thrusters, such as the T6 Qinetiq thrusters used on Bepi Colombo can generate up to 145 mN each ([Holste et al., 2020](#)). The T6 Qinetiq thruster is a Kaufman-type ion thruster using high density graphite in the accelerating grid ([Luna et al., 2017](#)). The graphite is conductive and stable in the presence of the active species in the plasma plume, minimizing erosion and potential back sputtering of material onto the craft in flight.

Cathode materials – Barium Oxide-Scandate ([Goebel and Katz, 2008](#)) is used in impregnated dispenser cathodes, while lanthanum hexaboride, LaB_6 , is formed as a single component (low work function and high electron emissivity) ([Goebel and Watkins, 2010](#)). While LaB_6 cathodes operate at higher temperatures than the BaO-W dispenser cathodes, it is more robust. As a single material source, there is more of the bulk emitting materials present, and it is able to handle higher current densities. Graphite sheaths can be used with LaB_6 cathodes to provide a low stress support and good electrical contact, while not being susceptible to boron diffusion or formation ([Chu and Goebel, 2012](#)). BN-SiO₂ and BN ([Levchenko et al., 2018](#)) ceramic insulating materials are utilized at the walls and around cathode. BN-SiO₂ and composite materials have been utilized in plasma chambers due to their superior erosion rates, thermal stability and thermal conductivity.

VASIMR

The Variable Specific Impulse Magneto-Plasma rocket is under development by Ad Astra Rocket Company (AARC, Houston, Texas, USA). It is an electric propulsion device composed of three stages: plasma generation using helicon waves, heating of the plasma by single-pass ion cyclotron resonance heating (ICRH), and detachment of the plasma in a magnetic nozzle, as illustrated in [Fig. 11](#). VASIMR produces high and variable specific impulse, which can optimize propellant usage efficiency ([Chang Diaz, 2001](#)). Compared to Hall thrusters, the VX-200 thruster can generate significantly higher thrust (6.7 N) ([de Faoite et al., 2016](#)). The configuration does not use electrodes or grids in contact with the plasma and can those utilize higher plasma temperature ranges. However, this puts a lot of thermal load on the structural and containment sections of the thruster ([Mulcahy et al., 2009](#); [de Faoite et al., 2014](#)). While still under development, the use of ceramics has been identified for areas such as the gas containment tube where the dielectric loss tangent or dissipation factor needs to be as low as possible under high temperature conditions. Comprehensive reviews of temperature dependent mechanical and thermal properties of potential dielectric ceramics that could be used is given in [de Faoite et al. \(2012\)](#) and [\(2013\)](#).

In addition, ceramics are used to make superconductors to create high field strength electromagnets of use for VASIMR and other magneto-plasma thrusters. Ceramic superconductors are used for generating magnetic fields with minimal losses, and for power transfer lines. Different combinations are being investigated with different cooling strategies but two examples are given by [Rey et al. \(2002\)](#) for multi-filamentary tape form containing Bi-2223 ($\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_x$) and [Patel \(2011\)](#) utilizing MgB_2 as the superconducting ceramic materials.

Windows and Mirrors

Three applications are considered: substrates for space-based telescope mirrors, windows for space vehicles, and cover glass for solar cells for use in spacecraft. These applications are described in turn below.

Glasses and glass-ceramics are used in a variety of space applications. The applications of glasses and glass-ceramics span from readily apparent applications such as windows for space vehicles to more unusual applications. These materials are used as substrates for, e.g., space-based telescope mirrors, missile radomes and cover-glass for solar cells. Glasses and glass-ceramics have a range of optical, electrical, and thermo-structural properties that make them the best-suited materials for numerous space applications.

Windows for Spacecraft

For windows for space vehicles, it is necessary to retain optical transparency. In the space environment, windows are exposed to short-wavelength photons, including UV, vacuum UV, X-rays, and gamma-rays, in addition to high energy particles. Prolonged exposure to these short-wavelength radiations can result in darkening of glass.

Fig. 12 The Cupola as seen by Steve Bowen during his spacewalk on 3 March 2011 (www.esa.int).

Fused silica has very good resistance to radiation-induced darkening relative to many other glasses. One striking example of a window in Space is in the Cupola section of the International Space Station (see Fig. 12). Similar to the approach used in the Space Shuttle, each window was constructed of three separate panes. These were fused silicate panes consisting of: a debris pane, redundant pressure pane, primary pressure pane: 2.5 and 3.7 cm thick for side and top window pressure panes, respectively (Burt and Christiansen, 2003).

Windows for re-entry spacecraft are subjected to a variety of extreme environmental conditions. These can include high levels of vibration and shock during launch, high aerodynamic and thermal loads during flight at high Mach level, and extreme thermal

loads during atmospheric re-entry, requiring combinations of different materials. For the Space Shuttle orbiter, the windows were composed of three separate panes of glass, the approach later adopted in the ISS Cupola. An inner pane of aluminosilicate glass, similar to that used for the X-15, was used as a pressure pane, to contain the pressure inside the cabin. The outermost pane was not subjected to the cabin pressure, and its role was to withstand the high temperature of over 700°C occurring during re-entry in addition to withstanding thermal shock (Miska, 1991). This outer pane was therefore made from either silica glass or Vycor glass (Corning, USA), due to its high glass transition temperature, excellent thermal shock resistance and low thermal expansion coefficient. A third pane between the inner pressure pane and outer thermal pane serves as a backup in case of failure of either the pressure or thermal pane. This backup pane is also made from silica glass and is significantly thicker than the pressure and thermal panes. Silica glass has good transmittance for UV light, from which the crew of a space vehicle need to be protected. The aluminosilicate glass pane effectively absorbs UV light and is therefore effective in shielding the crew from UV (Miska, 1991).

Mirror Substrates

Substrates for astronomical mirrors are required to have a very high level of dimensional stability. In addition, they must be capable of being polished to an extremely low surface roughness. It is also often required that the substrate be manufacturable in a very large size. For mirror substrates for use in space, the mirror substrate also has the requirement of having low mass. These materials requirements are very demanding and challenging to fulfill. Materials that have been used for in-space mirror substrates include glass and glass-ceramics.

In addition to low thermal expansion glasses and glass-ceramics, some ceramic materials are also attractive as mirror substrates. These include, but are not limited to, SiC, CeSiC[®], as well synthetic cordierite (magnesium iron aluminum silicates). These materials' high thermal conductivities, combined with low thermal expansion coefficients, act to minimize thermal gradients, thermal hysteresis effects, and associated thermal distortion. The principal advantage that ceramics can offer over low-CTE glasses is that manufacturing processes associated with mass reduction can be simplified (Hull *et al.*, 2018; Kamiya and Mizutani, 2018). For example, complex shaped components can be made from CeSiC (see Fig. 13). CeSiC[®] has a very high maximum operating temperature (maximum continuous use temperature of 1400°C). Other benefits of this material include its low density (2.65–2.70 g cm⁻³), and an extremely

low coefficient of thermal expansion (Kaneda *et al.*, 2010). HB-Cesic[®] is a hybrid carbon fiber-reinforced silicon carbide composite material used for mirror in cryogenic applications (Devilliers *et al.*, 2017).

Corning 7971 is an ultra-low expansion (ULE) glass. It exhibits a near-zero thermal expansion coefficient within the temperature range 5°C to 35°C . The material is a silicate glass containing the addition of 7.5% titania (Miska, 1991). Rather than being produced by melt-quenching, Corning 7971 is produced by chemical vapor deposition (CVD). Use of the CVD process rather than the conventional melt-quenching process allows very high purity to be attained and also allows very accurate control over the composition, although the manufacturing process is slow (Miska, 1991). The thermal expansion coefficient can be directly controlled through the titania concentration (Miska, 1991). To support the glass, a honeycomb structure is typically bonded to the backside, or as an interlayer between two glass pieces. This porous structure minimizes weight. Fusion bonding or frit soda glass can be utilized to adhere the glass to the core, and subsequent annealing undertaken to relief internal stress. The primary mirror of the Hubble Space Telescope (Fig. 14), for example, is made from Corning 7971 ULE glass using this method (Miska, 1991). This mirror is 2.4 m in diameter (and apparently 38 cm thick). The core uses a square-shaped arrangement of support ribs. Top and bottom glass sheets fused to the support structure are approximately 2.5 cm in thickness. Using this construction technique, the mass of the mirror is reduced from ≈ 3600 kg to ≈ 830 kg, or approximately 23% that of an equivalent solid glass mirror of the same dimensions.

In 1968 Schott AG produced a transparent glass-ceramic called Zerodur (ZERODUR[®]). This Lithium aluminosilicate glass-ceramic material has been employed for a number of very large telescope mirror substrates. These glass-ceramics are produced by heat-treatment of glasses of suitable composition, typically containing nucleating agents such as TiO_2 or ZrO_2 . The heat-treatment converts the glass to a glass-ceramic of high crystallinity (see Fig. 15). This glass-ceramic has an extremely low coefficient of thermal expansion, giving good dimensional stability required for telescope applications (Hull *et al.*, 2018). Mass of telescope substrates reduced by 70% using ZERODUR[®] as honeycomb-shaped holes can be milled out from the back, significantly reducing mass for satellites. ZERODUR[®] also used for the extensively in large ground-based telescope applications (Döhning *et al.*, 2009).

Solar Cell Cover Glass

Solar cells are used extensively in almost all satellites. Solar cells need to be protected from the space environment. The factors from which the solar cell must be protected include short wavelength UV radiation (which can damage solar cells), impacts of micrometeorites, and the damaging effects of atomic oxygen (Miska, 1991). As the protection material must be transparent to the wavelength band used for conversion of light to electricity, the cover material is generally a thin glass sheet. The two glass types that have been used for solar cell cover glass are fused silica glass and silicate glass doped with cerium. Ceria-doped borosilicate glass is commonly used with germanium-based solar cells (Beauchamp and Cutts, 2017). Cover glasses can also be coated to offer enhanced properties. Examples include: Anti-reflective coatings (single MgF_2 or multi-layer applied to front side); UV reflective coatings in the <350 nm range to reduce operating temperatures (applied as multi-layer to front side); Static dissipative or 'conductive' coatings (typically Indium Tin Oxide – ITO) but can reduce optical transparency; Infrared coatings to reduce operating temperatures (applied to backside of glass but not commonly used) (Beauchamp and Cutts, 2017).

(Eds.), *Proceedings of the 4th International Symposium on Advanced Optical Manufacturing and Testing Technologies: Large Mirrors and Telescopes*, vol. 7281. SPIE. (728103).

Tribological and Wear Applications

As mentioned in previous sections, the space environment poses a number of different problems for different functional elements of a craft. In terms of the moving mechanisms on a craft, the tribological performance of these mechanisms is particularly impacted by the vacuum and temperature fluctuations. As the mission life, scale and complexity has increased, the tribological considerations have had to adapt to keep up, illustrated in **Fig. 16** (Wen and Huang, 2018).

Bearings are used extensively in launchers and satellites, and the applications include bearings in pumps, motors, sliding and rotating hinges and deployment mechanisms, gears, amongst others. A sample of mechanisms and their operating environment is given in **Table 1**. Of note, is the range of speeds used in the different components. Due to the variety of speeds, the use of lubricants may not be possible. This is complicated further in the high vacuum environment of space, as well as temperature variations. Tribological solutions fall into two categories for space mechanisms: fluid (Ley *et al.*, 2009) and solid (Lince, 2020) lubricants.

Fluid lubricated systems are typically chosen for high rpm applications (Wen and Huang, 2018), while solid lubricants are used in low-speed systems. However, under vacuum, issues associated with fluid lubricants include evaporation, creep, outgassing and thermal and atomic oxygen degradation (Sathyan *et al.*, 2010). With lubricated bearing systems (using high molecular weight oils) the viscosity of the lubricant typically varies geometrically with temperature, becoming very viscous at low temperatures and may begin to vaporize/evaporate at higher temperatures. In contrast, lubricant-free or dry lubricant bearing systems may be used over wider temperature ranges. The mechanical loads on systems in space may be lower than those on Earth due to the microgravity conditions. In contrast, turbomachinery used in LREs may be required to operate under very high loads, at high speed, and extreme temperatures.

For solid lubricants, particularly metals, sublimation can be a factor at moderate and high temperatures (Dunn, 2016). Mechanisms such as hinges, gears, bearings and electrical contacts. Lubricants can sublime/outgas (Dunn, 2016). Testing of solid lubricants can be tricky as they are susceptible to moisture pick-up and fail prematurely when tested under atmospheric or partial vacuum conditions. Asperities and contact points will carry the full load without a lubricant and increase the coefficient of friction, wear rates and increase the likelihood of cold welding between metallic pairs. (Bhushan, 2008).

While the density of Si_3N_4 is less than half that of 440C stainless steel, the steel bearings, and TiC-coated steel bearings have a significantly greater thermal conductivity, enabling more efficient heat dissipation. Application of a ceramic coating to the bearing surface has a number of advantages such as chemical inertness and hardness differential. Both of these minimize the potential for cold-welding. Cold welding may occur if a solid solution can be formed between the contacting phases/materials, if the contacting materials have a similar crystal structure, if there is a weak oxide layer present on one or both materials, and/or if there are high contact pressures. High temperature missions like Bepi-Colombo also pose a risk for cold welding due to metal sublimation and cold welding in solar array mechanisms i.e. bearings, slip-rings and cables (Dunn, 2016). TiC-coated bearings were utilized to reduce the risk and minimize contact pressure deformations. Dissimilar pairs are important to minimize adhesive wear, galling and cold-welding (Lince, 2020). The application of ceramic coatings (TiC, TiN, and TiCN) to bearings is a preferred solution in space applications. However, due to the processing temperatures involved during the sputtering process, the bearings have to be rehardened and polished to restore sphericity. Temperatures are not as high for TiN sputtering but this material has a higher coefficient of friction than TiC and is susceptible to changes in coefficient of friction under vacuum (Dunn, 2016). Si_3N_4 bearings can be used to reduce heat generation and have improved heat transfer over TiC/440C bearings. As such, they can operate at high temperatures and speeds. Ceramic bearings are also less reactive and suitable for use with wet or solid lubricants.

Fig. 16 Growth of tribology advances in space. Reproduced from Kannel, J.W., Dufrane, K.F., 1986. Rolling element bearings in space. In: Proceedings of the 20th Aerospace Mechanisms Symposium, third ed. NASA CP-2423, pp. 121–132. Wen, S., Huang, P., 2018. Principles of Tribology, second ed. Singapore: John Wiley & Sons.

Table 1 Speed ranges and working conditions of some space components

Component	Rotational speed (rpm)	Working conditions
Gyroscope	8000–30,000	High speed, EHL of rolling contact bearing
Torque wheel	3000–10,000	Medium speed
Scanner device	400–1600	Medium and low speed
Tracking antenna	100	Low-speed, boundary lubrication
Reaction wheel	10	Low-speed, boundary lubrication
Filter wheel	< ± 10	Low-speed, boundary lubrication
Sensors	Minor swing	Low-speed, possible lubricating
Sliding ring	Several to 20,000	Large speed range; difficulty in lubricating at low speed

Note: Wen, S., Huang, P., 2018. Principles of Tribology, second ed. Singapore: John Wiley & Sons.

Hybrid bearing systems are combinations of dissimilar materials, such as metal/ceramic and polymer/ceramic. These can be used to minimize wear caused by the adhesive mechanism or cold welding (Ley *et al.*, 2009). Hybrid bearings were used as replacements for all-steel bearings with materials such as silicon nitride (Si_3N_4) or zirconium oxide (ZrO_2). These bearing systems are capable of operating at cryogenic temperatures and the lubricant within the system is the cryogenic liquid H_2 itself (Ley *et al.*, 2009). Switching to a hybrid bearing system increased the life of the turbopumps within the main engine of the Space Shuttle by a factor of 60 (MacDonald and Badescu, 2014).

Additive Manufacture of Ceramics

Additive manufacturing (AM) is a rapidly growing area and its use in space applications for bespoke, one-off pieces, rapid prototyping and ability to produce complex geometries will see it play a more critical role in the space sector over the coming years. AM research typically falls into three categories: metal, polymer and other; the latter, “other”, includes ceramics, cement and regolith (Sacco and Ki-Moon, 2019).

One area of continued development is the ISS where there is on-going research in the field of AM and low gravity production (Matson, 2012). The first polymer printer was installed in 2014, and there are on-going activities focused on the production of ZBLAN fiber optic cables on the ISS. ZBLAN (fluoride glass: $\text{ZrF}_4\text{-BaF}_2\text{-LaF}_3\text{-AlF}_3\text{-NaF}$) fiber optics produced in zero gravity has the advantage of reducing or removing defects associated with crystallization and phase separation that occur during manufacture in the presence of gravity (Kasap, 2018). Similarly, the reduced effect of gravity is being explored for the production of SiC turbine blades (Misra *et al.*, 2015). However, development activities have to be taken as precursors for part and process validation

(Dordlofva, 2020). Utilizing the polymer filament-style technique, bound powder filaments are being explored for the 3D printing of “green-body” components that are subsequently treated like metal-injection molding components i.e., de-bind to a “brown-body” state and sinter to densify to final finished part. This approach is currently being qualified for SiC, WC and Al_2O_3 thermoplastic filament components.

The range of ceramic materials that have been 3-D printed is increasing, and includes silicon carbide, aluminum oxide, zirconium dioxide, and silicon nitride, as well as composites of these materials. An extensive summary on the range of techniques used to manufacture high-performance ceramics is given by Wang *et al.* (2019). Zhang *et al.* (2020) summarize the use of zirconia and zirconia-based composites in aerospace applications, amongst others. Similar to other AM ceramic materials, minimizing defects and maximizing as-built density are limiting factors if extensive post processing is to be avoided. This requires manufacture at high pre-heat/build plate temperatures (1600°C) and controlled atmospheres (Zhang *et al.*, 2020).

As the technology evolves, crossover into other areas such as electric propulsion is inevitable as complex structures and geometries can be realized. One such area is the area of ion propulsion where the ability to fabricate new, complex geometries for one off applications may drive development as the range of ceramic precursor materials suitable for AM increases. The use of AM is already seeing use in rapid prototyping of metallic components (Guo *et al.*, 2019) for ion thrusters, as well as larger thruster components (Wermuth *et al.*, 2015).

The ability to establish a manned colony of the moon is limited by the infrastructure present to support life (Ghidini, 2018). While there are a number of options, including transporting of fully functional modules to be landed on the moon, the use of regolith to fabricate enclosures presents a natural, less energy intensive alternative. The European Space Agency is investigating how 3-D printing of components using lunar regolith could assist in supporting a base on the Moon. Some small components produced by Lithoz (Lithoz GmbH, Wien, Austria) with high print resolution as part of this study are shown in Fig. 17. Lunar regolith is a mixture of oxides, primarily silicon dioxide and aluminum oxide, in addition to iron oxides (Engelschön *et al.*, 2020). In order to produce 3-D prints, the simulated regolith is ground to a powder and sieved. The powder is then mixed with a UV sensitive binder. Layers of the components are deposited, and then cured by UV light. The completed component is then sintered to densify it. Material development research for this application is ongoing. The advantage of using this regolith material is that it can be 3D printed into the required shapes, and the resulting structure will provide a natural barrier against radiation and temperature fluctuations, Fig. 18 (Cesaretti *et al.*, 2014).

While additive manufacturing is typically associated with the production of finished components, it is also being used to support more traditional manufacturing such as sand and investment casting. AM is used in the fabrication of wax molds for investment casting with a replica of a complex component may be 3-D printed in wax. The wax article is then dipped in ceramic slurry, creating a hard shell around the wax which can then be easily melted out. Molten aluminum can then be cast into the ceramic mold. The lost-wax process is an ancient casting technique, but has been improved on by use of 3-D printing. Similarly, complex cores can be manufactured for the production of complex, hollow, turbine blades (Zhu *et al.*, 2019). The use of AM for the manufacture of large sand casting molds ($4 \times 2 \times 1$ m) has also added a new dimension to the production of large, one-off cast components. Ceramic and binders are used to “print” the negative of the component structure, but with an ability to finely control

Fig. 17 Components 3-D printed using simulated lunar regolith. Image from ESA (www.esa.int).

Fig. 18 ESA's 3D printed Lunar base concept (www.esa.int).

the position of gates and sprues (Aghaei Meibodi *et al.*, 2019), as well as include active sensors to monitor the effectiveness of the pore (Walker *et al.*, 2018).

Concluding Remarks

With the drive towards weight savings and increased component operating temperatures, ceramic materials are seeing an increased interest and utilization. Ceramic materials offer weight reduction, superior thermo-structural properties, and environmental durability in a wide range of applications.

The development of complex 3-D textile weaving techniques for preforms with multi-axis reinforcement is a key factor in developing Ceramic matrix composites (CMCs) with improved properties. CMCs are enabling reductions in rocket nozzle mass, enabling construction of reusable launch vehicles and reusable space planes. The extent of use of CMCs in space applications is increasing as the focus is shifting for demonstration to validation. CMCs and ceramics foams are key components in thermal protections surfaces on re-entry vehicles, as well as structural components in nozzles.

Advanced ceramics are seeing utilization in electrical propulsion, either as thermally stable, low erosion plasma facing surfaces, cathodes and accelerator grids or dielectric and super-conducting magnetic components.

Ceramics offer high thermal stability, making them the material of choice for re-entry surfaces. They also offer passive cooling solutions through their reflective and radiative properties. Over extended radiation exposure, ceramic solar reflector coatings are more stable under UV and particle radiation than organic matrix coatings.

The increased research in additive manufacturing and the combination of metal-injection molding post process, and ceramic-polymer filaments, promise new applications for ceramic materials. The ability to manufacture complex shapes, with functional cooling channels, already being seen in metals, is of particular interest. Simpler, open pore structures are already being manufactured in ceramic and these will serve to validate the processes for future applications.

Introduction

Porous ceramics are described as ceramics with high volume fraction of porosities between 20% and 95% and can be classified, according to the pore size, as microporous ceramics with pores less than 2 nm, mesoporous ceramics with pores of 2–50 nm and macroporous ceramics with pores larger than 50 nm (Liu and Chen, 2014). Hierarchically, porous ceramics contain pores of various length scales that are all combined in a single structured porous ceramic. The total porosity, pore size and shape of a porous ceramic can be tailored for the requirements in a targeted application by the geometry, the choice of materials and the manufacturing process (Akhtar *et al.*, 2014a,b). Porous ceramics are materials of industrial importance and are designed and structured in the form of honeycombs, foams, multilayers and membranes. These structured porous materials are widely used in liquid and gas filtration, particle filters and collectors, gas adsorption, hot metal filtration, water purification, dielectric resonators, biomedical implants, bioreactors, catalytic supports, automotive components, fuel cell assemblies, thermal insulations and refractories (Liu and Chen, 2014; Akhtar *et al.*, 2014a,b; Ohji and Fukushima, 2012). These broad applications in different industries are based on, (1) the properties of porous ceramics like high chemical and thermal stability, abrasion and wear resistance, mechanical and functional properties, (2) development of manufacturing approaches to shape ceramic components, and (3) knowledge development on tailoring of composition and microstructures in combination with optimum porous structure, pore sizes and distributions suitable for the targeted applications. Due to the difference in the properties amongst ceramics, oxide ceramics such as silica (Huo *et al.*, 2019), alumina (Ciurans Oset *et al.*, 2018; Hooshmand *et al.*, 2019), zirconia (Huo *et al.*, 2016), mullite (Choo *et al.*, 2019), cordierite (Li *et al.*, 2019), aluminosilicates (Alghamdi *et al.*, 2018; Ojuva *et al.*, 2013), carbide ceramics such as silicon carbide (Kultayeva *et al.*, 2020), nitride ceramics such as silicon nitride (Chun-fang and Bing, 2019) and recently high entropy boride ceramics (Chen *et al.*, 2019a,b) have been processed into porous ceramics for different applications.

In ceramic membranes, catalytic reactors and high temperature fuel cells or electrolyzers (solid oxide cells (SOCs)), the microstructure and pore architecture, such as pore size, pore structure and distribution of active phases/components, play a key role for achieving high performance in separation processes, catalytic processes (Keane, 2003) or to convert fuels into electricity or vice versa. Here we explain the importance of material choice, processing and microstructural design on the performance of advanced porous ceramic structures in three selected energy applications: catalysis, solid-oxide cells and membranes.

Catalysts

Porous ceramics have been directly employed as catalysts, for examples in the form of zeolites (Ennaert *et al.*, 2016), or as catalyst supports for noble metal catalysts, such as cordierite decorated with Pt, Rh catalysts for selective catalytic oxidation (Hung, 2010). Hierarchical porous ceramics in structured form offer the properties required to overcome the shortcoming of conventional catalytic beds and reactors. Porous ceramics used in exhaust treatments contain hierarchically porous structures with pore sizes in the range from 6 nm to 500 μm (Al-Naib, 2018).

Ceramics in catalysis can be used directly as catalyst or as support material for the active catalytic component. Ceramic catalysts are typically oxide ceramics such as transition metal oxides (TMO) (Wang *et al.*, 2018), microporous zeolites (Ennaert *et al.*, 2016) and perovskites (Voorhoeve *et al.*, 1977). The surface chemistry, pore and defect structure of ceramic oxide catalysts have been determined as important parameters for the catalytic performance (Keane, 2003). TMOs are oxides of transition metals (Ti, Ni, V, Cr, Zr etc.) with large variety of chemical composition ranging from mono-oxides to high entropy oxides and crystal structures that are used in different chemical applications, like the oxidation of CO (Chen *et al.*, 2018) and volatile organic compounds (VOCs) (Liu *et al.*, 2016). Zeolites are microporous aluminosilicate ceramics, FAU (Faujasite) and MFI (Mordenite Intervented Framework) type, with tailorable chemistry, crystal structure and porosity making these materials highly efficient for shape selective catalysts with broad applications in biomass conversion and petrochemical industry (Ennaert *et al.*, 2016; Vermeiren and Gilson, 2009). Perovskites are ceramic oxides, typically expressed as ABO_3 compounds, containing two metals A and B. These components have tailorable chemistry and structures depending on the type and size of the metals and are widely used in heterogeneous catalysis, functional layers in solid oxide fuel cells, as multilayer capacitors, piezoelectric transducers and superconductors (Keane, 2003). Porous ceramics are structured to carry catalytic active metals and offer large surface area, efficient mass and heat transfer properties, low pressure drop and appreciable mechanical strength for the enhancement of catalytic performance. The porous ceramic supports are structured in the form of granules, extrudates, honeycombs and laminates. The structured porous ceramics are optimized for their thermal, mechanical, chemical and mass transfer properties for specific catalytic applications (Akhtar *et al.*, 2014a,b).

Metal oxides, including Al_2O_3 , SiO_2 , CeO_2 , SnO_2 , ZrO_2 , are employed as effective catalysts and support materials (Akhtar *et al.*, 2014a,b; Keane, 2003; Alghamdi *et al.*, 2008). For instance, Al_2O_3 is an effective catalyst for double bond isomerization and it is widely used as support material for V_2O_5 for oxidative dehydrogenation of light alkanes (Liu *et al.*, 2016; Wu *et al.*, 2008). The

catalytic properties of metal oxides are dominated by surface and structural defects. Furthermore, metal oxides possess sites suitable for acid-base interactions. Acid-base properties of metal oxides are useful in catalytic oxidation of hydrocarbons, isomerization of olefins, dehydrogenation, and alkylations (Védrine, 2017; Sattler *et al.*, 2014). The redox properties where metal oxides undergo reduction and re-oxidation is well recognized in redox catalysis. Since surface properties and defects in metal oxides play an important role in catalytic reactions, several different processes and methods have been developed to synthesize metal oxide nanoparticles using gas condensation methods, spray pyrolysis, aerosol chemistry, oxidation of metal colloids, precipitation and sol-gel methods with tailored structure and properties (Keane, 2003; Astruc, 2020). The catalytic activity of the TMOs depends on a broad range of surface structures and features, originating from the allocation of metal cations and oxygen anions and structural defects. The crystal structure of TMOs depends on close-pack arrangement of oxygen anions, with metal cations covering interstitial sites. For instance, in mono-oxide, many TMO (TiO and NiO) have rocksalt structure, in which the octahedral sites have cations in an oxygen anion FCC array. The majority of TMOs (MO_2 ; $\text{M} = \text{Ti, Cr, V, Mn, Zr, Pd, etc.}$) have the rutile structure. The rutile structure is produced by filling half of the octahedral sites with cations of the HCP oxygen anion array. In trioxides, few TMOs can reach the +6 oxidation state (Dey *et al.*, 2019). The TMOs are relatively cheap and can be designed and tailored to offer high specific surface area, porosity, active surface sites and have been investigated in mono, mixed and composite catalyst preparation with enhanced performance in CO oxidation, formaldehyde and VOC oxidation (Wang *et al.*, 2018; Liu *et al.*, 2016; Dey *et al.*, 2019). Microporous ceramics, zeolites, are used in catalysis as support for noble metal catalysis in petrochemical industry as well as for shape selective catalysis due to their well defined and tailorable pore sizes and shapes and presence of strong acidic sites (Csicsery, 1984; Gläser and Weitkamp, 2004). Furthermore, microporous ceramics offer the possibilities to be processed into hierarchical structures to tailor the heat and mass transfer kinetics during a catalytic process. Microporous, mesoporous and macroporous ceramics are typically used as supports for catalytically active components. The structures are designed with tailored pores at various length scales to tailor the mass and heat transfer properties to deliver robust supports for catalytic reactions (Akhtar *et al.*, 2014a,b; Ohji and Fukushima, 2012).

Solid Oxide Cells (SOCs)

Solid oxide cells (SOCs) are environmentally friendly and highly efficient electrochemical devices for the conversion of fuels into electricity and vice versa. Solid oxide fuel cells (SOFCs) can convert electricity into fuels whereas solid oxide electrolysis cells (SOECs) can produce fuels from electricity, such as hydrogen. The operating principle of the SOCs and the involved electrochemical reactions in each operation mode are illustrated in Fig. 1. SOCs are multilayered structures containing porous and

Fig. 1 Illustration of the operation principles of 3 selected examples of applications of porous ceramics in advanced energy technologies. In the top and from left to right: Solid Oxide Cells (SOCs), ceramic membranes and catalysts. Typical architectures and microstructures for the technologies are shown in the middle and bottom rows.

dense layers. The essential components of the SOC are porous fuel electrode, dense electrolyte, porous oxygen electrode and the electrolyte, which separates the fuel electrode from the oxygen electrode. SOCs are typically operated in the temperature range of 600–1000°C. Different designs of the SOCs exist based on the supporting element. If the SOC is supported by the electrolyte, it is known as electrolyte supported SOC. If the SOC has a support layer made up of either fuel electrode material or oxygen electrode material, they are known as fuel electrode supported SOC (Fig. 1) or oxygen electrode supported SOC, respectively. Structurally, both the electrode supports and electrodes are porous in nature to facilitate the gas transport to the reaction interfaces. On the other hand, the electrolyte is a dense layer so that it can separate the gaseous species from fuel electrode and oxygen electrode sides. The pore size, pore size distribution and pore volume in the electrode supports and electrodes play a critical role in the mechanical stability and electrochemical performance of the SOCs, as they control the load bearing material volume, transport properties and reaction surface areas. Thus, the optimization of the microstructure/electrode structure plays a crucial role in developing highly efficient SOCs.

Based on geometry, the SOCs are divided into planar and tubular SOCs. The structural and transport requirements are similar in both planar and tubular configurations. In typical planar electrolyte supported SOCs, the electrolyte layer is much thicker (150–300 μm) compared to fuel electrode and oxygen electrode layers (typically 10–30 μm). In order to reduce the resistance of the electrolyte and improve the performance of the SOCs, architectures with thin electrolytes are developed, leading to electrode supported designs. In typical fuel electrode or oxygen electrode supported SOCs, an additional support layer made of fuel electrode material or oxygen electrode material is included. The support layer thickness is much higher (200–500 μm) compared to fuel electrode layer (10–20 μm), electrolyte layer (10–20 μm) and oxygen electrode layer (20–30 μm). Technologically relevant sizes of the planar SOCs can be in the range of 100 cm^2 to 600 cm^2 with different planar geometries. The tubular SOCs can have dimensions from few μm to mm in diameter and few mm to about 1.5–2 m in length, facilitating faster start-up and large power density depending on the dimensions of the tubes. Depending on the configurations, the fabrication process will be different and the details will be discussed in the Section on “Processing of Porous Ceramics”.

Due to the multilayer architecture of the SOC, consisting of different ceramic and metallic materials with different properties, careful attention must be paid to the appropriate selection of the materials. All components have to show a well matched thermal expansion behavior, chemical compatibility with other layers and chemical stability in the operating atmospheres. The performance of SOCs is not only determined by intrinsic material properties but also depends on the fabrication processes used and the resultant microstructures/porosity. The performance of SOCs can only be improved by using high performance materials in combination with appropriate fabrication methods. In terms of electron/ion transport properties of the porous electrodes, the fuel electrode can be electronic or mixed electronic and ionic conducting material and the oxygen electrode is a mixed electronic and ionic conducting material. A short description of the various fuel and oxygen electrode materials is provided.

Fuel electrode supports and electrodes: The mixture of NiO and Y_2O_3 doped ZrO_2 (YSZ), known as Ni/YSZ cermet, is widely used as the fuel electrode support and fuel electrode in the typical state of the art SOCs (Jiang and Chan, 2004). Ni, formed after reduction of NiO, acts as an electrocatalyst for the oxidation of H_2 and CO and as an electronic conductor, whereas the YSZ acts as a stabilizer for the porous electrode structure and extends the reaction interfaces due to its ionic conductivity. These materials exhibit superior electrochemical performance in general; however, they suffer from redox instability, impurity intolerance and high cost. As alternatives, various materials, such as, Fe-based metals/alloys or electronic conducting ceramics in combination with integrated electrocatalysts have been investigated. The use of Fe-based metals/alloys electrodes are mainly used in the metal supported SOC configuration and comes with a restriction of processing them in protective atmospheres due to their tendency of corrosion. Various perovskite and fluorite structured ceramic materials ($\text{Sr},\text{La})\text{TiO}_3$, $(\text{Sr},\text{Y})\text{TiO}_3$, $(\text{La},\text{Sr})(\text{Cr},\text{Mn})\text{O}_3$, (Tucker, 2010) $(\text{La},\text{Sr})\text{CrO}_3$, $(\text{La},\text{Sr})(\text{Al},\text{Mn})\text{O}_3$, $(\text{La},\text{Sr})(\text{Ti},\text{Mn})\text{O}_3$ (Atkinson *et al.*, 2004) have been investigated as materials for electrodes and electrode contact layers. These materials offer impurity tolerance and redox stability; however, the electrochemical performance is relatively poor due to the lack of sufficient electronic/ionic conductivity and electrocatalytic activity. Wide variety of materials are investigated as fuel electrodes (Sun and Stimming, 2007).

Oxygen electrode supports and electrodes: Perovskite (ABO_3) ceramic compounds (e.g., LaCoO_3 , LaMnO_3 , LaFeO_3 and LaCrO_3) with various A-site and B-site substitutions are widely used as oxygen electrode materials (Sun *et al.*, 2010). The La and Sr from these perovskite ceramics has a tendency to react with the YSZ electrolyte and form high resistance phases like $\text{La}_2\text{Zr}_2\text{O}_7$ and SrZrO_3 . In order to avoid these reactions, to match the thermal expansion behavior with electrolyte and to obtain required transport properties, various A-site and B-site substitutions have been investigated and suitable compositions identified. Furthermore, double perovskites, fluorites and composites of different material classes were also investigated (Kaur and Singh, 2020).

Ceramic Membranes for Liquid and Gas Separation

Porous ceramic membranes are used for separation processes in micro, ultra and nanofiltration that do not allow the use of polymeric membranes including wastewater treatment (Samaei *et al.*, 2018), desalination processes, pervaporation and gas separation (Tsuru, 2008). The exceptional chemical resistance, thermal stability and low fouling tendency make porous ceramic membranes ideal for operation at evaluated temperatures (above 100°C), at relevant application pressures (up to 10 bars and above) and under harsh chemical conditions (Vercauteren *et al.*, 1998). This includes the operation or “in-place cleaning” of ceramic membranes in the entire pH range from 0 to 14 and in organic solvents without the risk for membrane compaction or swelling with chemicals such as ozone, hydrogen peroxide, strong inorganic acids or steam, for example in water treatment of

Fig. 2 Type and size of particles and the membrane separation processes to separate them according to their size. From Xu, Q., Zhang, W., 2016. Next-generation graphene-based membranes for gas separation and water purifications. In: Silva, A., Carabineiro, S. (Eds.), *Advances in Carbon Nanostructures*. IntechOpen. doi:10.5772/64396.

highly concentrated organic effluents, such as oil and grease (Madaeni *et al.*, 2013), brackish water, seawater pre-treatment and high temperature desalination (Amin *et al.*, 2016). Disadvantages of ceramic membranes are challenges in handling due to their brittleness and the significantly higher material and fabrication costs compared to polymer membranes.

Fig. 2 summarizes examples of applications for membranes, which can be classified after the pore sizes to achieve the separation task. For more challenging applications, such as nanofiltration, reverse osmosis, pervaporation or gas separation, small pores with very well-defined sizes between 0.1 nm and 10 nm are required. Alternatively, asymmetric dense ceramic membranes are developed for gas separation, based on zeolites (Kosinov *et al.*, 2016), on mixed-conducting materials that transport oxygen ions at high temperatures (Sunarso *et al.*, 2008) or on proton conducting materials (Tao *et al.*, 2015). The driving force for gas transport across the membranes is a chemical potential gradient. The separation or transport mechanism depends on the pore size (and chemistry) of membrane and the size of gas molecules and can include Knudsen diffusion (or activated or surface diffusion), size exclusion (molecular sieving) or solution-dissolution for the dense membranes (van den Berg and Smolders, 1992).

Oxides of alumina, silica, titania and zirconia are the most common ceramic membrane materials for advanced separation processes in wastewater treatment, nanofiltration and gas separation (Tsuru, 2008). According to the requirements of specific applications and operation conditions, membranes are produced in different geometries (see **Fig. 1**), such as plates, tubes or hollow fibers. From these materials, asymmetric membranes can be produced in the form of multi-layer structures based on a macro-porous support and a sequence of different macro, micro and mesoporous layers, depending on the required pore size of the final membrane layer for the separation task (middle, bottom part of **Fig. 1**). Similarly, hierarchically porous multilayer architectures can be used to support dense thin-film ceramic membranes for gas separation, such as zeolite membranes (Caro, 2011), oxygen transport membranes (Ramachandran *et al.*, 2015; Sunarso *et al.*, 2008) or proton conducting membranes (Cai *et al.*, 2009). The fabrication of porous asymmetric membranes includes the basic steps of ceramic processing, mass preparation, shaping and sintering, as outlined in the following section.

Processing of Porous Ceramics

The processing of porous ceramics has been extensively investigated and several methods have been matured for industrial production. The simplest way to process is dry pressing followed by partial sintering to achieve a porous component with around 45% porosity. In the simplest approach, the porosity is mainly controlled by the particle size and shape of the starting ceramic powders. In order to have better control over size and shape of pores and total porosity, several processing approaches have been developed to process ceramics with tailored microstructure required for specific applications. The fabrication of porous ceramics can be classified according to the flow behavior (viscosity) of the ceramic mass, as colloid, plastic or dry forming processes. Typically, the processing of porous ceramics involves mixing of the ceramic component in a solvent (most commonly water) with organic and/or inorganic binder, templating agents (to produce pores) and additional organic additives (e.g., plasticizers, demolding agents). Organic binders are typically added to facilitate the processing of green bodies and offer mechanical integrity and stability to undergo further processing, while inorganic binders can be added in some processes (applications) to bind particles of the ceramic component during the sintering process to impart strength (Akhtar *et al.*, 2014a,b; Ohji and Fukushima, 2012; Hammel *et al.*, 2014). Excess sacrificial binder can also be added to create porosity. Other templating agents are introduced to add additional porosity and pore size to optimize the density and mass and heat transfer properties of the resulting porous ceramic scaffolds. The templates are chosen based on the processing approach, final density of the component, total porosity, shape and size of pores, ease of removal, stress development in the components during removal and environmental impact

Fig. 3 Overview of different processing methods for shaping of porous ceramics, used in catalysis, solid oxide cells (SOC) and ceramic membranes.

(Keane, 2003; Ciurans Oset *et al.*, 2018; Hooshmand *et al.*, 2019). Once all the components are mixed homogeneously, a shaping operation is performed e.g., molding, granulation, die casting, freeze casting, gel-casting etc., to produce the desired engineering structure. After shaping, a debinding step is carried out to remove organic components and templating agents followed by final consolidation and sintering for mechanical stability. Some commonly used processes for the structuring of macroporous ceramics are foaming, extrusion, slip and tape casting, gel casting, coating, spray drying, and dry pressing. In the case of microporous ceramics such as zeolites, the sintering parameters such as temperature and time are of significance as the higher temperature and time results in destruction of internal porous structure. Therefore, the technology is based on the addition of inorganic binder such as clays and silica to sinter at lower temperatures to preserve micropores (Keane, 2003). Recent work has been focused on the development of binderless approaches for microporous ceramics including (1) conversion of clay binder using hydrothermal process to micro-mesoporous ceramics and (2) consolidation by pulsed current processing by applying pressure and temperature to consolidate by forming mechanically stable bonds by local amorphization. 3D printing has gained significant attention to process 3D structures and has been successfully implemented to design macroscopic ceramic components with hierarchy of pores using traditional and microporous ceramics (Chen *et al.*, 2019a,b; Zocca *et al.*, 2015). A brief description of the most commonly used processing approaches is summarized in the following sections (Fig. 3).

Dry Pressing

Dry pressing of ceramics is a fast-industrial mass production technique based on the axial compaction of loosely granulated ceramic powders with a moisture content below 3% by the force of punches in a die. In uniaxial pressing, usually a top and bottom punch are used. Due to relatively low concentration of organic additives in the powder granulates, the time for removal of organics during the debinding step can be shortened and parts with low tolerances are achieved. For the fabrication of porous ceramics, considerable amounts of sacrificial templates (pore formers) need to be added to create porosity when removed during the heat treatment process. Dry pressing is for example used for isostatic or hot isostatic pressing of porous ceramic filters, catalyst or membrane supports.

Extrusion

Extrusion is a plastic forming process used industrially to shape ceramic components of a fixed, cross-sectional profile by compacting and pushing a ceramic mass with high pressure through a cylindrical barrel and finally through a die. As the plastic mass exits the die it has the desired cross section and can be cut into sections of the desired cross section and length, resulting in honeycombs or rods as catalyst supports or support tubes for SOFC or membranes (Richerson and Lee, 2018; Reed, 1995).

Extrusion has been adopted for processing of hierarchically porous ceramics using traditional and microporous ceramics. The important steps in extrusion are the preparation of ceramic paste containing organic binder and solvent with suitable rheological properties for flowing through a barrel and die system. The extrusion gives great flexibility in designing and tailoring porous ceramic components. Another approach adopted is to extrude the ceramic substrate and deposit a coating of an active catalysts by film growth or by colloidal processing. For catalytic support materials, the extruded substrates can be categorized as low surface area and high surface area substrates. These extruded substrates are used in automotive, chemical processing, oxidation, catalytic combustion and emission control reactors. The commonly used ceramics for extrusion of low surface area substrates are cordierite, mullite, silica and alumina. Zeolites, titania, vanadia, precious and rare-earth metals are supported on these substrates for catalytic application, using film growth, infiltration and washcoat methods (Hung, 2010; Lefevre *et al.*, 2013; Kašpar *et al.*, 2003). High surface area monoliths are extruded using zeolites and high surface area oxides in the form of granules, pellets and extrudates. Similar processing operations are used for high surface area substrates. However, the sintering is performed carefully to keep the

high surface area intact during sintering operation. Furthermore, high surface area monoliths can be catalytically active in case of zeolites and can be decorated with catalysts to enhance the performance. Different types of oxide/carbide materials (Al_2O_3 , SiC, YSZ or MgO), have been specifically developed and extruded into macroporous, mechanically stable and permeable ceramic support tubes for use in advanced multilayer membranes in nanofiltration and gas separation applications (Ramachandran *et al.*, 2014; Buekenhoudt, 2008).

Colloidal Processing

Colloidal processing encompasses a variety of processing methods to shape porous ceramic supports, catalyst structures and electrocatalytic layers for energy applications at industrial scale and include a range of methods such as slip casting, tape casting, freeze casting or dip coating. The colloidal processing can be adjusted to shape ceramics with a targeted type of pore size, pore geometry, tortuosity and surface area. In order to apply the colloidal processing methods for shaping, a suspension of the ceramic component is prepared with controlled and optimized rheological properties with dispersing agent, organic and/or inorganic binders, plasticizers and antifoaming agents. The interparticle forces between the ceramic particles in the suspensions are tailored for optimization of rheological behavior for the process chosen. Colloidal processing techniques are versatile for shaping.

Gel casting has been used widely to process porous alumina, silica, zirconia, coeorderite ceramics and have been extended to zeolites 13X, silicalite-1 (Keane, 2003). Additional templates have been added to impart additional macroporosity and directional channels in porous zeolites (Akhtar *et al.*, 2012a,b; Wang *et al.*, 2016a,b). Structured alumina substrates with controlled porosity, pore size and shape have been demonstrated using expandable polymer microspheres of different sizes using gel casting (Ciurans Oset *et al.*, 2018; Hooshmand *et al.*, 2019).

The tape casting process is a well established ceramic processing technique to produce two dimensional dense and porous layers with a typical thickness between 5 μm and 1 mm (Mistler and Twiname, 2000). Due to this capability of making layers of different thickness and the ability to control the porosity in the layer, this process can be used for the fabrication of different type of layers, for example macro porous support layers (Schmidt *et al.*, 2016) or mesoporous electrocatalytic layers (fuel or air electrodes) or dense layers in planar SOC or membrane reactors (Kaiser *et al.*, 2011). Furthermore, tape casting allows continuous, industrial scalable fabrication of these layers. The key for a defect free layer fabrication is the optimization of the slurry formulation. Tape casting slurries usually consist of ceramic powder, solvent, dispersant, homogenizer, plasticizer and binder. By controlling the amounts of these ingredients, one can design slurry formulations that are suitable to produce layers of different thickness, pore size and pore volume. In addition to this, the casting parameters such as casting height, speed and rate of drying need to be optimized for defect free layer fabrication. The layers can be casted individually and laminated together or can be co-casted together to realize complete multilayer structure in one step. Subsequently, these multilayered assemblies are subjected to organics removal and sintering steps to obtain the final structure.

Screen printing is a well-established mass manufacturing technique to deposit different ceramic materials as thick-film layers (5–100 μm in thickness) on various support materials, for example in glass, electronic and semiconducting industry. Examples include the printing of decals on glasses, coatings in photovoltaics, deposition of electrolytes and electrodes in planar solid oxide cells (SOC) and membranes (Rotureau *et al.*, 2005). In screen printing, a mesh or screen is used to transfer a ceramic ink onto a substrate by a moving squeegee. First the ink is pushed into the open apertures of a mesh and then transferred to a substrate during the reverse stroke of the squeegee while the screen gets in contact with the substrate. A good understanding of the complex relation between the composition of highly loaded inks, their rheology (flow behavior, thixotropy) and the screen-printing parameters during the different printing phases is very important to ensure the fabrication of screen printed layers with accurate dimensions and quality after printing and low dimensional changes during sintering (Phair *et al.*, 2009).

The sol–gel process is a wet chemical technique, in which small metal oxide particles, especially silicon oxide (SiO_2) and titanium oxide (TiO_2), are produced from small precursor molecules (metal alkoxides or salts). The precursor materials undergo a transformation into a colloidal solution (sol) by hydrolysis and condensation reactions with a morphology of the solid phase between an integrated network (or gel) or discrete particles (Brinker and Scherer, 2013).

The three basic steps of hydrolysis and condensation are schematically shown for silicon alkoxides in Eqs. (1–3), according to Brinker (1988)

The process is extensively used and of crucial importance for the fabrication of meso- and microporous layers in ultra-, nanofiltration and gas separation membranes. Furthermore, depending on the speed of hydrolysis and condensation and the used solvent, two routes can be distinguished - the colloidal Sol-Gel route and the polymeric Sol-Gel route. The use of these techniques for the fabrication of very thin porous membrane separation layers with pore sizes down to the angstrom range are discussed in more detail in the section on ceramic membranes for liquid and gas separation.

In dip-coating a liquid film with a thickness between 10 nm and 10 μm is usually deposited on a support by immersion in a Sol-Gel precursor solution or a slurry (Puetz and Aegerter, 2004). After removal of the support with a constant speed, the deposited film is dried through evaporation of the liquid. Finally, a debinding and sintering step is performed (Brinker, 2013). Multiple

coatings with very controlled thickness, porosity and pore size distribution have been applied in porous and dense membranes for liquid and gas separation applications (Ramachandran *et al.*, 2015; Yin *et al.*, 2018). For more details, see Section “Ceramic Membranes for Liquid and Gas Separation”.

Advanced Processing Techniques

Templating

Templating strategies are implemented to create pores at various length scales in porous ceramics ranging from pores of gas molecule sizes, micropores, to large macropores. Templating strategies can be subdivided into soft templating and hard templating. Soft templates used are polymers, surfactants, emulsions, foaming agents and solvents. The soft templating is used to process porous ceramics with mesopores and macropores. A combination of soft templates and solvents can be chosen to produce hierarchical structures containing micro-mesopores and macropores. Hard templating produces porous structures by incorporating solid in the synthesis solution. After templating, the templates are removed by solvent extraction and thermal treatment methods to obtain a negative replica of the template to achieve porous structures. Templating methods have been widely adopted to process porous ceramics of coeenderite, alumina, zirconia, silicon nitride and so on. Zeolites, aluminosilicates, and silicoalumino silicates and meso porous ceramics have also been processed using hard templates and hierarchically porous structures combining different templates (Akhtar *et al.*, 2012a,b, 2014a,b).

Physical vapor deposition (PVD)

PVD methods use the concept of evaporation of a material, which is deposited and condensed onto a substrate. The evaporation sources can be thermal, electric arc, electron beam and laser ablation. Among other things, the energy of the evaporation source, distance between the evaporation source and the type of deposition substrate are the key process parameters that can control the quality of the deposited coatings. More advanced SOC designs, known as μ -SOCs, and ultra-thin separation membranes, where the porous layers are very thin, are areas where these processes are used. Often another supporting element is used in these designs. Often the material to be deposited is in the gaseous or liquid state before coating deposition. PVD methods, particularly laser ablation (Xu *et al.*, 2020), are often used to deposit the thin electrolytes, fuel and oxygen electrodes in advanced SOC designs and ultra-thin nanoporous membrane layers.

Freeze casting

Freeze casting is a processing technique that exploits the anisotropic freezing characteristic of water (or other solvent) to fabricate the porous ceramics. A well dispersed aqueous ceramic slurry is subjected to a controlled temperature gradient to directionally freeze the water. The freezing of water reorganizes the ceramic particles creating templated porous ceramics. The resultant structure is freeze dried to remove the ice crystals and subsequently sintered at appropriate temperature to realize the robust porous ceramic structure. The underlying principles of porous structure formation mechanisms are provided here (Dewille, 2008). The applicability of the process for the SOC designs is discussed in detail (Hedayat *et al.*, 2017). The process is also investigated for the fabrication of ultrafiltration alumina membranes (Liu *et al.*, 2018).

Phase inversion techniques

Phase inversion techniques (immersion precipitation) can produce porous ceramic structures with large, unidirectional pores and is based on an exchange between a solvent (typically N-methyl-2-pyrrolidone, NMP) and a non-solvent/coagulant (typically water) from a slurry. This process is induced when the shaped ceramic body (for example a porous ceramic capillary membrane) is directly introduced into water. The phase inversion then starts by the solvent NMP dissolving from the slurry. A skin layer on the outside of the shaped body is formed. Subsequently, water slowly penetrates the skin layer, enters into the slurry and acts as a nucleation site for exchange of the solvent (NMP) by the non-solvent (water). This exchange process will result in the growth of large pore channels (“finger-like” pores) perpendicular to the skin layer and stops when the solvent and non-solvent diffusion rates have equilibrated. Phase inversion tape casting has been used to develop high performance micro channelled oxygen transport membranes (Cheng *et al.*, 2016).

Novel processing approaches

New processing strategies are emerging for conventional and microporous ceramics. For instance, zeolites are structured using binderless processing to remove the inactive component to reduce inactive component effecting the catalytic performance and structural integrity. The binderless approaches are pulsed current processing of microporous ceramics and conventional ceramic processing followed by hydrothermal treatment to convert inactive components to zeolitic materials (Akhtar *et al.*, 2012a,b, 2014a,b). 3D printing has been gaining attention to structure ceramics with well controlled porous structure and kinetics. 3D printing, commonly termed as additive manufacturing, has been applied to structure monoliths and has potential to replace conventional catalysts and chemical reactors (Chen *et al.*, 2019a,b; Zocca *et al.*, 2015).

Sintering of Porous Ceramics

Sintering is an important final heat treatment step in the fabrication of porous ceramics. The aim is to give the ceramic body sufficient mechanical strength and to achieve a morphological structure with a very well defined grain and pore size by controlling the grain and pore growth in sintering of porous ceramics. The sintering is a process in which the ceramic material tries to reduce the surface energy (Gibbs free energy) by diffusion processes under application of temperature. In the initial sintering stage, at low sintering temperatures T_s well below the melting point of the material T_m ($T_s < 0.5 T_m$), necks are formed between particles by surface diffusion. In the 2nd stage, at sintering temperatures of T_s near the melting point T_m ($T_s \sim 0.5\text{--}0.9 T_m$), grain boundary diffusion starts and leads to grain growth. Larger particles tend to eat the smaller particles because they have a more pronounced curvature and higher surface energy. This process leads to grain growth and formation of larger pores with an overall decrease in total porosity and total surface area. In the final stage of sintering, at temperatures close to the melting point, bulk diffusion leads to full densification of the porous ceramic body by eliminating the last 5%–10% of pores. For the fabrication of porous ceramics, usually heat treatment and temperatures are controlled to limit grain boundary and bulk diffusion phenomena that lead to pore elimination and significant densification.

Structure – Performance Relationship in Porous Ceramics for Energy Devices

Porous Ceramic Catalysts

Structured porous ceramic catalysts are designed with a hierarchy of pores to offer advantages of lower pressure drop, high surface-to-volume ratio, and optimized heat transfer properties and mechanical strength (Akhtar *et al.*, 2014a,b; Lefevre *et al.*, 2014). Catalysts in industrial applications are shaped in the form of granules, extrudates and pellets of different sizes for packing of catalytic beds. The packing of catalytic beds is applicable for (1) metal supported catalysts and (2) zeolite catalysts. However, the traditional shaping and bed packing leads to pressure drop, poor mass transfer kinetics, higher residence time of the reactant and product species, and catalyst deactivation happens at a faster rate. These properties are tailored by controlling the size of the shaped catalyst and controlling the particle size in the shaped entity and porosity distribution to improve performance. Structured catalysts combine Macro-Meso-Micro pores in a structure and typically shaped in form of monoliths, honeycombs, laminates to tailor the mass and heat transfer properties with optimized pressure drop and diffusion while offering mechanically stable structures (Akhtar *et al.*, 2014a,b). This approach has become increasingly important in supported catalysts and zeolite catalyst where structure and properties are optimized with superior catalytic performance and longer lifetime of the active component. The understanding of the structured materials with tailored porosity has been developing and structured packings has been demonstrated in ceramic monoliths with straight channels (Lefevre *et al.*, 2014; Matoh *et al.*, 2019), sheet/gauze metallic packings with catalysts coatings (Rebrov *et al.*, 2001), open cell ceramic foams (Twigg and Richardson, 2007) and 3D printed catalyst support structures with optimizing the architecture of the support combining good mass and heat transfer properties with low pressure drop (Lefevre *et al.*, 2013, 2014).

Catalysts carriers ceramic monoliths

The application of catalytic supports are used in various catalytic applications including petrochemical industry, carbon dioxide conversion, catalytic converters. The porous ceramic scaffolds are decorated with metal nanoparticles. The scaffolds are structured with tailored porosities and properties. Metal nanoparticles are introduced by wash coating, impregnations, precipitation, dip coating, sol-gel and in situ crystallization (Keane, 2003). A key factor in processing the support with the active components is to achieve a strong bond between the catalyst and support to avoid deactivation of catalysts. A classic composition for vehicle exhaust treatment with a washcoat consists of a Al_2O_3 support, a $\text{CeO}_2\text{--ZrO}_2$ mixed oxide, barium/lanthanide oxides as alumina surface area stabilizers and the active metal component Rh, Pt, and Pd (Keane, 2003; Hung, 2010; Kašpar *et al.*, 2003). The geometry of the support is important in determining the catalytic converter performance (Keane, 2003; Lefevre *et al.*, 2013; Kašpar *et al.*, 2003). In some other applications, the shape selectivity of a zeolite is combined with metal catalysts by using the zeolite as support for the metals. For example, hierarchical mesoporous Pd/ZSM-5 zeolite has been used for the selective catalytic hydrogenation of *m*-Cresol to methylcyclohexane, in which the mesoporous ZSM-5 enhances the accessibility for Pd metal and increases the selectivity towards the desired deoxygenated product (Hunns *et al.*, 2016). Similarly Pt/ZSM-5 catalysts with shape selective properties for partial hydrogenation of soybean oil have been reported (Van Aelst *et al.*, 2016).

Zeolite catalysis

Zeolites are aluminosilicates that occur naturally or can be synthesized in the laboratory. Zeolites have made significant contribution in petrochemical and chemical industry as shape and size selective catalyst for hydrocarbon conversion (Csicsery, 1984; Dusselier and Davis, 2018). The performance of zeolites is due to their crystalline framework structures and uniform pore sizes of molecular dimensions and excellent thermal and chemical stability (Akhtar *et al.*, 2014a,b; Keane, 2003; Hedin *et al.*, 2010). Furthermore, a variety of pore sizes exist in zeolites to implement the shape selectivity by carefully choosing a zeolite for catalytic reactions. The size of the zeolite pore window is determined by oxygen in the ring. For instance normal hexane with a kinetic diameter of 5.1 Å can pass through a 10 membered ring zeolite whereas cyclohexane with a kinetic diameter of 6.9 Å would have a

Fig. 4 Layered zeolite materials. Reproduced from Choi, M., Na, K., Kim, J., *et al.*, 2009. Stable single-unit-cell nanosheets of zeolite MFI as active and long-lived catalysts. *Nature* 461, 246–249.

restricted transport through a 10 membered ring zeolite (Jae *et al.*, 2011). The pore sizes are tailorable, defects in zeolites are controllable and methods have been established for structuring of zeolite into macroscopic bodies with hierarchical porosity, which have led to increased performance in many important catalytic reactions, such as cracking, isomerization, alkylation, biomass conversion, methanol to gasoline and olefins and oxidation reactions (Keane, 2003; Vermeiren and Gilson, 2009; Jae *et al.*, 2011; Serrano *et al.*, 2013; Čejka *et al.*, 2016). Zeolite have been designed and synthesized with pore sizes larger than 1 nm with high activity. The large pore zeolites of interest have pores larger than 12 ring zeolites. The hierarchical zeolites are synthesized by modifying the synthesis chemistry and/or by post treatment (Serrano *et al.*, 2013). The breakthrough in zeolite synthesis was made with the synthesis of layered crystals and even monolayer assemblies (Fig. 4). The layered zeolites have potential to replace currently used zeolites in alkylation, dehydration and condensation and less susceptibility to coking and deactivation during catalytic processes (Wang *et al.*, 2016a,b).

Solid Oxide Cell Technology

Structure – Property relationships in SOC

As described in the Section on “Solid Oxide Cells”, together with the material transport properties, the pore size, pore size distribution and pore volume are the key parameters in achieving an efficient performance from the electrodes and electrode support layers. In order to achieve a critical control over the porosity in these layers, several approaches are incorporated into the fabrication methods described in the Section on “Processing of Porous Ceramics”. Some of these approaches are use of poroformers, foaming in the slurries, and adjustment of ceramic power characteristics, partial sintering, reaction sintering and templating. Carefully tailored micro-structure (size, morphology and orientation of grains and pores, etc.) of porous ceramics has led to unique mechanical properties, which cannot be attained even in the dense materials.

Electrode support layers: The electrode support layers should facilitate the transport of the gas molecules to the reaction interfaces at the electrode-electrolyte interfaces, provide the mechanical stability and should possess the required electronic conductivity. Thus, these layers should have large enough pores for the easy gas transport, low enough pore volume to possess required mechanical strength and electronic conductivity, as both these are material volume dependent. Furthermore, the pore size distribution also influences the mechanical strength and conductivity. In addition, these layers should be free of any macro-defects as they severely affect the mechanical stability. Such requirements on the pore characteristics can be realized through the careful optimization of slurry formulations, use of pore formers, adjustment of ceramic powder physical characteristics (such as particle size, surface area) and optimizing the sintering parameters (Pihlatie *et al.*, 2009).

Electrodes: Both the fuel and oxygen electrodes should facilitate the transport of the gas molecules to the reaction interfaces at the electrode-electrolyte interfaces. These electrode structures do not bear any mechanical load and thus the mechanical strength of the layer is not critical. The electronic and ionic transport through the electrodes is a critical parameter in the efficiency of the electrode. Furthermore, the surface area of the electrode, particularly in the mixed electronic and ionic conducting electrodes, decides the reaction surface area and thus, the small pores (high surface area) are preferred. Higher reaction surfaces does result in higher electrochemical performance of the SOCs. Thus, the pores in the electrodes should be of the size that can easily transport the gases, while maintaining high surface area for the highest possible reaction surface area. The pore size, size distribution and pore volume becomes very critical, particularly for the electrodes that requires integration of additional electrocatalytically active materials. For example, the perovskite based fuel electrode materials discussed earlier may not possess sufficient electrocatalytic

activity and thus require integration of other material into these electrodes. Such requirements to enhance the electrochemical performance of the SOCs need the electrodes to have larger pore sizes and higher pore volumes so that these additional catalytic materials can be accommodated inside these pores.

Ceramic Membranes for Liquid and Gas Separation

Performance requirements and characterization of ceramic membranes

Porous ceramic membranes need to fulfill a couple of performance requirements, including mechanical robustness (mechanical strength), high thermal stability, permeability and selectivity. These properties can be determined by static and dynamic methods.

Dynamic methods, include the performance characterization in operation and can be described by few key performance indicators, the productivity (flux, permeability and permeance) and separation ability (including selectivity and separation factors). A detailed description of these parameters can be found elsewhere (Zwolinski *et al.*, 1949; Tan and Rodrigue, 2019).

With *static characterization methods* the microstructure (pore size, pore size distribution, microdefects), surface chemistry and mechanical properties of the membrane can be described. Membrane fabrication is a key step to control these membrane properties that may directly impact the final operational membrane performance. For further details, a couple of different techniques are available for microstructural characterization, including scanning electron microscopy (SEM), atomic force microscopy (AFM) and transmission electron microscopy (TEM) (Tan and Rodrigue, 2019), X-ray computer microtomography (micro-CT), nuclear magnetic resonance (NMR) and small angle neutron scattering methods (SESANS, MSANS) (Tylkowski and Tsibranska, 2015; Anovitz and Cole, 2015).

Relationship between processing, structure and performance of porous membrane layers

For achieving the desired properties of ceramic membranes for high performance in nanofiltration or gas separation, the careful, stepwise fabrication of defect-free hierarchical porous multilayer structures is of crucial importance. As described earlier, the most common membrane architectures consist of a porous support, intermediate layers and separation layers.

The membrane supports are usually prepared from micron sized raw powders by forming them into plates, monoliths, tubes or microtubes by using shaping methods, such as tape casting, slip casting, pressing, extrusion or spinning, and finally sintering them into macroporous bodies. In the case of extruded, tubular supports, wall thicknesses are in the range of millimeters to achieve sufficient mechanical strength with pore sizes usually in the range of several micrometers, supplying sufficient mechanical strength and high permeability (and low pressure drop). Such supports are usually not used directly for high performance separation of small particles in nm size or for gas molecules due to their large pore size and low selectivity and need to be coated with additional layers to gradually reduce the pore size towards the targeted membrane applications (see Fig. 2).

Intermediate and membrane separation layers are usually applied in 3 major steps: (1) the preparation of adequate slurries or sols, (2) the deposition of the layer by dip coating as interlayers or separation layers on the porous support tube and (3) separate thermal treatment of each dried slurry or gel layer. The number of layers that need to be applied on the membrane support, depends on the application requirements for the last layer, which is the membrane separation layer and its pore size determines the separation quality (see Fig. 1).

The permeability of the membrane depends on the porosity, pore tortuosity, pore morphology and thickness of the separation layer(s). Smaller pores and reduced layer thickness are required with increasing demand on the separation size, precision and selectivity from micro to nanofiltration and gas separation, requiring increasing demands on the quality of the coating processes.

In an asymmetric ceramic membrane, usually the first intermediate layer has the function to bridge the (tubular) support structure and the following separation layers with a slurry coating of ceramic particles that are large enough to avoid the penetration of the large pores and particles on the surface of the support and cover them homogeneously. This reduces the risk of the formation of coating defects, such as cracks or pinholes in the separation layers.

The most common way to adapt and process membrane separation layers towards more demanding commercial applications, such as microporous layers for nanofiltration or gas and vapor separation, is the use of carefully chosen sol-gel processes. Alternative coating processes have also been developed for the preparation of membrane layers for special materials and separation tasks, for example chemical vapor deposition (Nomura *et al.*, 2005), hydrothermal synthesis (Jiang *et al.*, 2004), anodic oxidation of alumina (Itoh *et al.*, 1996) and phase separation and leaching (Kukizaki and Nakashima, 2004).

The Sol-Gel method in combination with dip coating is the most common process to form ultrathin meso and microporous layers of ceramic materials with high (compositional) homogeneity, tailored pore size with narrow pore size distribution and stability under pressure and temperature. Depending on the requirements and fineness of the final membrane separation layer, two main routes can be distinguished for the Sol-Gel fabrication of thin film separation layers for ceramic membranes:

In the *colloidal Sol-Gel route*, the hydrolysis and condensation reaction of the precursor material(s) is relatively fast and done in aqueous solution by adjusting the reaction conditions (catalyst, pH, molar ratio of water and speed of addition) to achieve a fully hydrolyzed precursor. The fast condensation reaction results in the formation of particle growth and/or aggregation. For this reason, the control of very small sizes of the particles in the Sol in the nm range or below, which is required for the fabrication of microporous gas separation layers, is challenging.

In the *polymeric Sol-Gel route*, the hydrolysis and condensation of the precursor materials is slower because it is performed in organic solvents, using alkoxide precursors and slowly adding small amounts of water, resulting in partial hydrolysis and the

Table 1 Examples for materials, heat treatment and resulting pore diameter in different type of layers in asymmetric alumina-based membranes

Layer type	Sintering temperature range [°C]	Typical average pore diameter	Typical material
Support	1300–1500	1–10 μm	α -alumina
Slurry layer(s)	700–1300	0.1–1 μm	Boehmite or α -alumina
Sol-Gel layer(s)	600–1000	1 nm to 50 nm	γ -alumina and colloidal SiO_2
Sol-Gel layer	350–600	<2 nm	Polymeric SiO_2

formation of a more gel type network structure. Since the size of the particulates in the gel network is smaller, the polymeric Sol-Gel route, can lead to microporous separation layers, with pore sizes in the range of nanometers and below.

For the sintering of the membrane layers, preferably oxides with relative high melting point (oxides of alumina, silica, titania and zirconia) are chosen to ensure sufficient thermal stability during operation. These layers are then heat treated well below the melting point of the respective oxides to ensure neck formation between the fine particles during the initial phase of sintering. For the second stage of sintering primarily surface diffusion is promoted whereas grain boundary diffusion or bulk diffusion is suppressed to minimize pore growth.

Table 1 summarizes the typical sintering procedure for the different layers in a multi-layer alumina based asymmetric membrane, including materials, ranges of sintering temperatures, and pore diameters for the different layers.

Starting from a macro porous tubular α -alumina support, meso and microporous layers are applied by dip coating of alumina slurries and different alumina and SiO_2 sols and separate sintering. With each layer, the sintering temperature, the particle size, pore size and layer thickness are gradually reduced. During the debinding and sintering, the temperature profile of each layer needs to be adjusted very accurately to avoid the formation of any drying and sintering defects, for example the formation of larger pores, pinholes, cracks or delamination. The exact control of these coating and sintering steps is therefore essential to ensure a defect free microporous membrane layer with exact pore size (distribution) in the nm or Å range to achieve high selectivity and permeability of the membrane for example in nanofiltration or gas separation processes.

Summary and Outlook

Increasing demand for porous ceramics with improved performance in energy applications has already led to the development of new materials, advanced fabrication methods and resulting microstructures. However, new and emerging energy applications put increasing demands on porous ceramics with even better properties and performance based on the critical control of pore size and architecture, mechanical properties and chemical/thermal stability. Here, the tailoring of properties and precise control of the pore size, pore volume and microstructure by careful selection of materials and fabrication methods plays an important role to enable substantially new applications for porous ceramics or to help the breakthrough of new, emerging energy technologies. In energy applications, such progress has been demonstrated in the areas of catalysis, in ceramic membranes or in high temperature ceramic fuel cells and electrolyzers.

Joining of Advanced Ceramics

John A Fernie, Materials Processing Institute, Middlesbrough, United Kingdom

Kevin M Knowles, University of Cambridge, Cambridge, United Kingdom

Introduction

Joining is generally accepted as one of the key enabling technologies for the implementation of advanced ceramics. It facilitates the use of advanced ceramics by providing a means of manufacturing structures or components which cannot be made (commercially) in one piece, or which can be made less expensively, or with added functionality, via joining.

In the vast majority of applications for advanced ceramics there is a need to effect a joint in some way, i.e., to attach, fix, fasten or adhere one material/component to another. This can be the joining of relatively simple shapes of the same ceramic material to make a more complex geometry – and although there are examples of this, it is relatively rare. More common is the need to join dissimilar materials. Sometimes this can be dissimilar ceramics, but more frequently it involves the joining of a ceramic to either an organic polymer or a metal. There can be numerous reasons for this. Usually, there is a need for different functionalities in an assembly. A simple example would be a ceramic knife for domestic applications. The ceramic is needed as a blade for cutting, whereas the sheath for handling the knife is usually made from a cheaper and more easily formable material, such as a polymer. However, more commonly the ceramic must be joined to a metal. There are many examples of this in industry, i.e., in cutting tools, electrical insulators, and biomedical implants.

It cannot be overstated that if the joint is not suitable for the application for which it is intended, the component is very likely to fail prematurely in service, or even in manufacture.

There is a surprisingly wide array of methods to join ceramics to themselves and to other materials. Note, the term “welding” is avoided. Welding generally refers to joining processes in which both “parent” materials are substantially melted at the *faying surfaces*, i.e., the surfaces to be joined. A substantial heat affected zone (HAZ) is also produced. Such large-scale microstructural and physical disruption rarely occurs when joining ceramics.

Methods for joining ceramics range from mechanical attachment, such as bolting, screw threading and shrink-fitting, where joints are made without the formation of atomic or molecular bonds, to chemical methods, whereby a bond is formed via interatomic level interactions. In turn, chemical methods are usually sub-divided into solid-state and liquid-state methods. However, there are several processes which do not fit neatly into these relatively restrictive definitions and can be considered as hybrid techniques, such as ultrasonic bonding, which is a combination of mechanical and solid-state chemical bonding. For this reason, it may be convenient to consider a spectrum of joining technologies, such as the one shown in Fig. 1.

A number of joining processes are shown in Fig. 1; all are applicable to ceramic–metal combinations and most are applicable to ceramic–ceramic combinations. Fewer are applicable to ceramic–polymer combinations, usually because of the temperature limitations of organic polymers. It is the method of production of the interface between the materials which is considered in Fig. 1. Factors such as design and any differences in the coefficient of thermal expansion (CTE) are not considered. However, such factors are crucial, particularly when designing assemblies/components which must be fit for purpose. Joint design is discussed below.

Mechanical Methods

It is possible to join ceramics via mechanical methods, such as mechanical interlocking, bolts and/or screw threads (Fig. 2). Usually, such designs are only recommended if the final component does not experience arduous service conditions, such as thermal excursions or high shear/torque loading. Machining holes and threads into ceramics is costly, even if most of the work is done in the green (unfired) state. In addition, sharp changes in section and re-entry features, such as those associated with screw threads, should be avoided because they tend to act as stress concentrators. Exceptions to this general philosophy include ceramic knives and scissors (Fig. 2(b)) which frequently have plastic handles attached to a ceramic, most commonly zirconia or alumina, through a combination of mechanical fixing and organic adhesives.

Fig. 1 The joining spectrum.

Fig. 2 (a) Silicon nitride rod with a machined-in screw thread and (b) zirconia scissors showing machined-in holes.

Fig. 3 (a) Automotive spark plug and (b) a wire drawing die with a zirconia insert.

By contrast, automotive spark plugs are manufactured using a mechanical fastening technique which utilizes the difference in CTE between a ceramic and a metal, i.e., shrink fitting. An outer steel casing is heated and placed around the ceramic (alumina) insulator. On cooling, this contracts around the ceramic, so clamping it and placing it in compression. The assembly is shown schematically in **Fig. 3(a)**. Note the presence of compliant interface layers, which in this case are made from aluminum, a low modulus material, in the form of inserts at key points, to absorb stress concentrations induced at sharp corners and changes of section.

Other examples of shrink fitting are found in general engineering as wire drawing dies using zirconia as the insert in a steel housing (**Fig. 3(b)**), and in the biomaterials sector as femoral heads in hip replacements.

Thermomechanical Processes (Hybrid Processes)

There are processes which are best described as thermomechanical, i.e., a hybrid between mechanical and chemical, in that they are produced as a combination of frictional heat and solid phase bonding. These processes are only viable for ceramic-metal combinations, and then only when the metal has a low elastic modulus. Examples include ultrasonic bonding and friction welding.

In ultrasonic bonding, a soft metal, such as aluminum, in the form of a thin foil (typically < 2 mm thick), is joined to a ceramic using an ultrasonic horn. The bond is formed using acoustic waves transmitted via the horn, with typical frequencies between 15–20 kHz and wavelengths of 20–30 μm , along with an applied pressure of 10–30 MPa and bond times of ~ 1 –10 s. During bonding, plastic deformation of the metal, coupled with rupture of surface oxide films, brings atomically clean metal into contact with the ceramic. Mechanical keying then occurs, along with some chemical interactions, to provide a bond. Typical applications are found in Na–S batteries, where Al is joined and sealed to β -alumina.

Friction welding, almost always referred to as a welding technology, although strictly incorrect as no melting of the parent material occurs, is similar to ultrasonic bonding in that a soft metal (again aluminum is the most common) is brought into contact with a ceramic. In this case, the metal, usually in the form of rod typically 1–4 mm in diameter, is rotated and then brought into contact within the ceramic at room temperature. Frictional heat is generated, producing high temperatures at the interface, sufficient to allow plastic deformation of the metal. Rotation then stops within a few seconds and a uniaxial pressure is applied. The metal plastically deforms, and a bond is formed. A flash (collar or upset) is also produced, which beneficially contains many of the surface oxides and inclusions present on the original surface of the metal; this is usually machined away.

Both ultrasonic bonding and friction welding processes are characterized by very sharp interfaces. Joining is postulated to occur via a mechanism in which a combination of local frictional heat and plastic deformation of the metal lead to the creation of a mainly mechanical bond, coupled with a diffusion bond, but only over a distance of a few atomic layers. Although there is little evidence of

Fig. 4 Generic set-up for uniaxial diffusion bonding.

such diffusion or chemical bonding, bond strengths, even though they are modest, are higher than would be expected from purely “mechanical/friction” adhesion, i.e., “scrubbing” the relatively soft metal around irregularities or into pores in the ceramic surface.

Chemical Methods

There are several chemical methods available for the joining of ceramics. Conventionally, these are described either as solid-phase or liquid-phase, although there are also hybrid techniques. The chemical joining of ceramics, even to similar materials, is “difficult”. This is because of their strong ionic or covalent bonding and the low self-diffusivity of the constituent atoms. This contrasts with the nature of bonding in polymeric and metallic materials.

Therefore, by definition, one of the major considerations in the joining of ceramics to dissimilar materials is how to control the nature of the interface, i.e., the differences in atomic bonding. This consideration, combined with differences in CTE, which can cause excessive strains in a joint line if not designed correctly, are the two main concerns when implementing chemical methods for joining ceramics.

Solid Phase Methods

The hybrid thermomechanical processes discussed above for ceramic–metal combinations both rely on mechanical deformation of the metal, with a modest contribution from diffusion. Conventional solid phase methods for joining ceramics also rely on the same principle of initial mechanical deformation, but combined with a significant contribution from diffusion processes.

Ceramic–ceramic diffusion bonding

Diffusion bonding (DB) is a “solid phase/state” process that induces coalescence of the faying surfaces by the simultaneous application of heat and pressure over a period of time. The process does not involve large macroscopic deformation of the parent materials. Instead, it uses a combination of interdiffusion between the grains of the ceramic(s), together with a softening of any secondary intergranular (glassy) phases. In its optimized form, a diffusion bond between similar ceramics is invisible.

A simplification of the set-up for diffusion bonding is shown in [Fig. 4](#), where two blocks of the same ceramic material are to be uniaxially diffusion bonded.

When uniaxially diffusion bonding two similar ceramics, a “suitable” pressure is applied, generally between 1–20 MPa, at temperatures approximately 0.5–0.8 T_m , where T_m is the melting or softening temperature in K. Diffusion takes too long if the temperature is too low, and if the temperature is too high, there is the possibility of excessive plastic deformation of the whole assembly. Bond duration is dependent on load/pressure and temperature but is typically 30–120 min. The majority of bonds are produced in vacuum; better than 10^{-3} mbar is recommended.

A “suitable” load/pressure is one which allows micro-deformation at the faying surfaces, sufficient to eliminate asperities and bring a larger area of surface together in contact to allow diffusion, but not enough to cause macroscopic buckling or deformation of the whole assembly. The primary process parameters for diffusion bonding are time, temperature and pressure. Other factors such as surface cleanliness (in all chemical bonding processes, faying surfaces should be free from dirt, grease, fingerprints and any other contaminants) and “flatness” are also crucial.

It is important to understand the relationship between roughness and surface flatness, or waviness. For example, the way [Fig. 4](#) is drawn implies that the surfaces to be bonded are smooth, parallel and flat at an optical level, and this is indeed the ideal scenario. However, most machined surfaces have a bimodal distribution of surface roughness. There is the fine-scale surface roughness, frequently described in terms of asperities; this fine-scale surface roughness is usually measured using conventional techniques such as profilometry and represented as R_a . However, there is also the larger-scale roughness associated with undulating or wavy surfaces. These two surface distributions are shown schematically in different physical situations in [Fig. 5](#).

In the situation shown at (a) in [Fig. 5](#), interfacial contact is between two perfectly flat and parallel surfaces; this is the ideal scenario. At (b), the surfaces are parallel, but both contain fine-scale asperities. In principle, this sample should bond successfully,

Fig. 5 Examples of surface profiles.

Fig. 6 Alumina–alumina diffusion bond produced using microwave radiation (2.54 GHz) as a heating source.

but there would be a defect in the upper surface: the particularly large depression in the upper surface shown in (b) would be retained after joining. At (c), both surfaces have fine-scale asperities, but both surfaces are too wavy. This bimodal distribution of fine-scale surface roughness and surface waviness is generally unacceptable. Smooth, but wavy, surfaces, such as those shown schematically in (d) will not bond satisfactorily because not enough material would come into contact at the faying surfaces irrespective of the R_a values of the two surfaces. Finally, if as in (e), the surfaces are misaligned, bonding will not occur other than at local contact points.

In practice, the scenario shown schematically in (b) is the most common. Although the scenario in (a) would be ideal, it is seldom economically viable to machine surfaces to this level of flatness. It is commonly accepted that R_a should be less than $0.4\ \mu\text{m}$. A diffusion bond between two 94 wt% Al_2O_3 ceramic rods is shown in **Fig. 6**.

Ceramic–metal diffusion bonding

Ceramics can be bonded to metals using solid phase diffusion bonding. The process parameters are broadly the same as those for ceramic–ceramic bonding, but the mechanism is slightly different because the ceramic has much higher compressive yield stress than the metal. Under these circumstances, the “harder” ceramic surface can force deformation of the asperities of the softer metal during the initial stages of the process. A schematic representation of the process is given in **Fig. 7**.

In (a) in **Fig. 7**, the hard ceramic surface and the comparatively soft metal surface come into contact at asperities of the two surfaces. In (b), the asperities on the metal surface are plastically deformed, so that the ceramic asperities indent (locally) the metal surface. Deformation of the metal continues, as in (c), coupled with diffusional mass transfer, leading to shrinkage of the interfacial voids between the metal and the ceramic. Further diffusional flow within the metal enables a bond to be formed, as in (d), with little or no residual porosity at the joint.

Use of thin interlayers to enhance diffusion bonding

The quality of a diffusion bond can usually be improved by increasing any or all of the primary process parameters, i.e., time, temperature and load/pressure. However, if increasing these parameters is likely to cause irreversible harm to the assembly/component, such as buckling, then the use of interlayers to enhance bonding should be considered. In this context, an interlayer refers to a material whose purpose is to promote solid state diffusion, and hence bonding. Usually, this is a thin layer of metal typically $< 25\ \mu\text{m}$ thick with a low elastic modulus and/or a high atomic diffusivity. (In a different context, the term interlayer can also refer to a material used to overcome CTE mismatches when bonding dissimilar materials. Under these circumstances, the interlayer is usually much thicker, up to several millimeters thick; this is discussed later in Joint Design).

Interlayers to enhance diffusion bonding can be applied as thin coatings $< 10\ \mu\text{m}$ in thickness via electroplating or vapor deposition/sputtering, for example, or they can be pre-placed in the form of foils, usually around $25\ \mu\text{m}$ thick. Chosen

Fig. 7 (a)–(d): Sequence of events during ceramic–metal diffusion bonding.

correctly, interlayers can reduce bonding temperatures, negate excessive surface roughness and alleviate small differences in CTE. However, if a poor choice is made, interlayers can decrease the temperature capability and strength of the bond, and cause issues with corrosion.

Advantages and disadvantages of diffusion bonding

The main advantage of diffusion bonding is that joints can be produced with properties and microstructures very close to those of the parent materials. In addition, diffusion bonding produces no plastic (gross) deformation of the component, so that there is no need for subsequent machining.

The primary disadvantages are the thermal cycle time, even though a number of bonds can be produced simultaneously, and the relative expense of the diffusion bonding equipment, i.e., it is a specialized process.

Hybrid Chemical Processes

Anodic bonding

Anodic bonding has been used to join metals and/or semiconductors to glass with similar CTE, e.g., silicon to Pyrex. Also referred to as field-assisted bonding, electrostatic bonding and Mallory bonding, anodic bonding is similar to diffusion bonding. However, in this process, there is an additional parameter: a d.c. voltage is applied across the materials to be bonded during the process, which induces a strong electrostatic attraction at the interface.

The initial condition of the faying surfaces is critical to the process. Unless the surfaces mate very closely and are very smooth, the bond produced will not be hermetic. The surfaces must have $R_a < 0.05 \mu\text{m}$. The materials to be joined are then heated to a suitable temperature below the softening points of the materials, but high enough for ionic conduction to occur. A typical bonding temperature is about 450°C . A d.c. voltage (1000 V) is applied so that the metal or semiconductor component is at a positive potential relative to the glass, i.e., so that the metal or semiconductor is on the anode side and the glass is on the cathode side of the surfaces to be bonded.

At temperatures between $300\text{--}500^\circ\text{C}$, the cations in the glass, such as sodium ions, are relatively mobile, and on application of a voltage, move away from the interface towards the cathode. This produces a cation-depleted layer at the surface of the glass. The voltage drop across the gap between the silicon and glass causes an electrostatic force which helps to bring the two surfaces together. The force increases as the joint gap decreases, so there is a driving force to bring the two surfaces together. Therefore, where there are points of initial good contact, these will extend outwards, eventually bonding the whole surface. In silicon–Pyrex anodic bonds, oxygen migrating from the Pyrex “reacts” with silicon to form a $\sim 10 \text{ nm}$ thick amorphous silica interfacial reaction layer which constitutes the final bond.

Gas–metal eutectic bonding

A variant of ceramic–metal diffusion bonding occurs when, at the appropriate bonding temperature, the contact between the faying surfaces favors the formation of a liquid phase. This is generally known as gas–metal eutectic bonding.

The best known and most widely used type of gas–metal eutectic bonding is *direct copper bonding*. The process involves heating a copper foil in contact with alumina in a controlled, i.e., slightly oxidizing, gas atmosphere at a temperature of 1070°C . Under these conditions, the surface of the copper oxidizes and forms a eutectic liquid. This can be explained by referring to the phase diagram in Fig. 8. The eutectic liquid reacts with the alumina and, on solidification, a copper aluminate phase is formed at the interface, producing a bond between the copper and the alumina. The process is used extensively in the electronics industry as a means of joining high thermal conductivity copper to alumina substrates.

One variant of this technique is to use pre-oxidized copper; a second variant is to use pre-oxidized aluminum nitride as a high thermal conductivity substrate.

Fig. 8 Cu–O phase diagram and an electronic substrate (alumina–copper) made by direct copper bonding.

Fig. 9 The Houskeeper process and a typical component.

Glass-to-Metal Bonding and Sealing

Glass-to-metal sealing can be regarded as a liquid phase or fusion technique. The glass is heated to a semi-molten state above its glass transition temperature, T_g , while in contact with the metal. Bonding occurs via wetting and chemical reaction. Glass-to-metal seals are easy to manufacture either in batches or as part of a continuous process. They are relatively inexpensive to produce and can provide highly reliable, hermetic seals with good strength under moderate thermal and mechanical loadings.

The Houskeeper seal is one of the earliest examples of glass-to-metal seals for technical application. Houskeeper seals are used to join glass tubes to copper tubes. A schematic of the design of these seals is shown in Fig. 9 together with an example of a seal. The success of the design is reliant on the metal being relatively ductile; copper is the most common example. Typically, a copper tube is first tapered at the end to be joined. A glass is then brought into contact with the thinned metal and heated to above its softening point. On cooling, as the glass contracts onto the copper, the copper physically yields, absorbing any strains induced in the glass during the process. For this reason, the Houskeeper seal is an example of what is termed a “ductile” glass-to-metal seal.

Glasses can be bonded to metals to form hermetic seals for many other applications. These include electrical feed-through connectors, solid-oxide fuel cells, and biomedical implants. Electrical feed-through connectors are of particular commercial interest; these consist of electrically conducting metal pins enclosed within an electrically insulating glass, which in turn is enclosed in a metal housing. The function of the glass is to provide electrical isolation for the pins, both from other pins and also from the housing, and to protect the system from the external environment, and therefore moisture, for example. A glass-to-metal feed-through assembly is shown in Fig. 10.

There are a wide number of glasses capable of, and in some cases designed for, bonding to metal. Silicate-based glasses and glass-ceramics are commonly used in conjunction with a stainless steel housing and pins. For example, the lithium zinc silicate system has been widely reported as a glass exhibiting good sealing compatibility with stainless steels. An advantage of this system is that the CTE can be tailored, so permitting close match to a range of metals and alloys.

The sealing of glass to various materials, including other glasses, is dependent on the relationship between temperature and viscosity, the differing thermal expansion characteristics of the components to be sealed, the wetting and adhesion characteristics of the molten glass at sealing temperatures, and the chemical durability of the glass during service.

As well as the nature of any chemical bonding, the mechanical integrity of a glass-to-metal seal is dependent on the stress state at the interface(s). Glass-to-metal seals are usually categorized as either matched or compressive. In a matched seal, the CTE of each material is similar. However, in a compression seal, the CTE of the glass is higher than the pin, but lower than the housing. Compression seals are typically stronger than matched seals because the chemical bonding is accompanied by compressive hoop stresses in the glass from the surrounding metal. For matched seals, sealing is predominantly a result of good chemical bonding at the glass-metal interface.

Fig. 10 Glass-to-metal feed-through assembly.

Fig. 11 Schematic of a single pin glass-to-metal seal with idealized bonding models.

Fig. 12 Types and classification of glass-to-metal seals.

The glass parts are frequently supplied (commercially) as preforms, made by compressing glass powder into the desired shape. The metal pins should be capable of being oxidized so that the oxide layer produced adheres well to the metal. The oxide should also be able to be wet by, and be dissolved by, the glass at elevated temperature to produce a transition reaction layer between the glass and metal with good mechanical strength, as in the schematics in Fig. 11. This transition reaction layer constitutes the bond. It is important to control the thickness of the oxide on the metal. If the layer is too thin, then on dissolution into the glass, the bond with the parent metal will be lost. This will result in a weak bond and a probable loss of hermeticity. If the oxide is too thick, then on completion of the joining cycle, an excessive amount of oxide may remain undissolved, leading to a relatively weak bond.

Seals are generally described and referred to in terms of: the geometry of the metal parts, type of metal or alloy, type of glass, type of joining method, the fabrication technique, or relative thermal expansion of the glass and metal (Fig. 12). The most frequently used classification is based on the last of these; this is then sub-divided based on the type of glass, type of metal, and so on. Matched seals are sub-divided according to the expansion of the glass, and therefore the metal or alloy. Glasses such as borosilicate glasses and vitreous silica with CTEs $< 6 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$ are designated hard glasses. Those such as soda-lime-silica glasses with CTEs $> 6 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$ are designated soft glasses.

Liquid Phase Methods

The most widely used methods for joining ceramics are based on liquid phase processes whereby a third body (the joining medium or adherend) is placed between the faying surfaces. There are a range of such technologies and media available for these methods, ranging in temperature capability from organic adhesives to metallic solders and brazes, glasses and glass-ceramics and ceramic adhesives.

Fig. 13 (a) A spherical cap of liquid, L, in equilibrium, on the surface of a solid, S, above which there is a gaseous region, V, likely to contain the vapor of the liquid, (b) examples of wetting on silicon nitride with Ag–Cu–Ti (left-hand side) and Ag–Cu eutectic (right-hand side).

In nearly all cases the joining medium is placed between the surfaces to be joined and the assembly is heated. This is either to cure the medium, in the case of organic adhesives, and/or melt it, in the case of solders and brazes, to produce the bond. Liquid phase bonding has many practical advantages. Probably the most important of these is the ability of the liquid to be able to flow and fill the joint gap at the faying surfaces completely, even if the individual surfaces are relatively rough and there are relatively large voids in the contact region. Some degree of surface roughness is actually desirable in terms of mechanical keying for strength in shear, particularly for organic adhesives and inorganic “ceramic” adhesives.

In general, liquid phase bonding is quicker than diffusion (solid-state) bonding. However, it should be appreciated that it is common for the joint created in liquid phase bonding to be the weakest link in the assembly. It should also be appreciated that the ability of the liquid to flow over and “wet” the surfaces is critical in enabling bonds of sufficient strength to be formed. Most liquids in contact with a ceramic surface will tend to ball-up. This is rarely advantageous. Therefore, before the various liquid phase methods are described for advanced ceramics, it is relevant to highlight those aspects of wetting behavior of liquids on solids, and particularly ceramics, which are of relevance.

Fundamentals of wetting

As mentioned above, a liquid on the surface of a ceramic will tend to ball up. Therefore, it is necessary to induce the liquid to wet and flow across the surface of the ceramic. A suitable diagram to use to describe wetting of a solid by a liquid is shown in Fig. 13(a). In this diagram, a spherical cap of liquid, L, is in contact with a solid, S, above which there is V, the precise nature of which depends on the ambient environment, but it is usually air, a vacuum or inert gas, which, in reality, is also likely to contain vapor of the liquid. Experiments undertaken to examine wetting of liquids on solids, particularly in the context of liquid metals on ceramics, are termed sessile drop experiments. Examples of results from such sessile drop experiments are shown in Fig. 13(b).

Atoms at a surface of a liquid or solid are deprived of some of their neighbors relative to those in the interior of the liquid or solid, as a consequence of which there is an energy penalty for liquids and solids associated with the creation of a surface in contact with a vacuum, or in contact with another liquid or solid. These energy penalties are known as surface energies, γ , defined as the work that can be obtained from the destruction of unit area of surface, with units of N m^{-1} , i.e., a force per unit length, as shown in Fig. 13(a). The magnitudes of surface energies are determined by the appropriate intermolecular forces; typically, those for metals and ceramics are at least an order of magnitude greater than for organic molecules and polymers.

From Fig. 13(a), treating the surface energies as forces per unit length and resolving horizontally,

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta$$

(Young's equation), where θ is the equilibrium contact angle. For L to wet S, θ should be as low as possible. By convention, $\theta < 90^\circ$ is considered to define a wetting condition, whereas $\theta > 90^\circ$ is considered non-wetting.

Another useful concept is the *work of adhesion*, W_A , which is related to the surface energies according to the Dupré equation. This is the work per unit area which has to be done to separate the liquid from the solid, and is equal to the lowering of the overall free energy per unit area through wetting:

$$W_A = \gamma_{SV} + \gamma_{LV} - \gamma_{SL}$$

An interface is stable when W_A is positive, i.e., forming the interface lowers the total free energy per unit area of the system. In terms of the contact angle θ , W_A can be written as the Young–Dupré equation:

$$W_A = \gamma_{LV}(1 + \cos \theta)$$

The situation shown in Fig. 13(a) and described by the Young–Dupré equation is an over-simplification for a number of liquid phase methods for joining advanced ceramics because it does not take into account any chemical reactions which might occur between the metal and ceramic. If a reaction takes place, one or more new compounds can form, which may well enhance wetting and adhesion, as in active metal brazing.

Organic adhesives

Adhesives, “glues” or “cements” are non-metallic compounds which are able to spread over a surface to be joined. Therefore, for such joining media when in their liquid form, $\theta < 90^\circ$. It is usual not to have to manipulate the relevant surface energies to achieve wetting. However, prior to joining, the faying surfaces should be cleaned, so that they are free from organic and inorganic contaminants such as dust, moisture or weakly adsorbed organic material.

In general, an organic adhesive is a polymeric material having chemical and physical properties differing from those of the base materials, placed at their faying surfaces, to join the materials together as a result of the attractive forces of this polymeric material.

Polymer-based, organic adhesives represent a relatively straightforward method of joining ceramics to a range of metals, ceramics and other polymeric (plastic) materials. A range of organic adhesives are available, based predominantly on epoxy resins, acrylic adhesives, cyanoacrylate adhesives (“superglues”) and silicones. Such adhesives can be used in applications where the interface (adhesive) service temperature is below $\sim 200^\circ\text{C}$. Above this temperature, unless the adhesive is very well protected, it will char and degrade.

Despite their limitations, organic adhesives offer several advantages. From a commercial perspective they are usually relatively low cost and easy to apply, requiring little or no special equipment or training. From an engineering perspective, an organic adhesive tends to distribute an applied load evenly along the bond-line. The relatively low elastic modulus of organic adhesives enables them to accommodate thermally induced strains. Organic adhesives find use mostly in the traditional ceramics and electronics and photonics sectors, and for other ambient temperature applications such as ceramic knives, in which partially stabilized zirconia blades are joined by organic adhesives to handles made from a variety of materials.

Soldering and brazing

As the temperature requirements of an interface increase, soldering and brazing find widespread use. Typical applications are in machining to bond cutting tools to suitable substrates and in the power electronics industry to join ceramic substrates to copper heat sinks. Soldering and brazing are processes in which a metal or alloy is placed in between the faying surfaces. The metal is frequently in the form of a foil $\sim 50\text{--}100\ \mu\text{m}$ thick. These foils are available commercially, as are equivalent pastes and powders.

The fundamental difference between soldering and brazing is the melting point or liquidus of the material. If the liquidus is below 450°C , the process is termed soldering, while if the liquidus is above 450°C , the process is termed brazing. The bond is assembled and then heated, usually in a vacuum. On heating, the solder or braze melts and a bond is formed. The key is the ability of the solder or braze to wet the ceramic.

Metallization – methods of making a ceramic surface wettable by a liquid metal

Key to the success of liquid phase bonding methods is the ability of the interlayer material to wet and react chemically with the faying surfaces.

There are four basic approaches to induce a liquid metal to wet a ceramic surface. These are:

- (1) The metal hydride process;
- (2) Vapor deposition techniques;
- (3) Sintered metal powder processing (SMPP);
- (4) Active metal brazing (AMB).

In the first of these processes, a paint, typically titanium hydride, together with a powdered solder or copper is deposited onto a ceramic and then heated in an inert atmosphere to produce a metallized coating on the ceramic. In the second of these approaches, a thin layer of metal is deposited onto the ceramic using vapor deposition from a plasma, i.e., by sputtering, rendering it wettable. However, these two techniques are rarely used commercially. By far the most dominant processes are SMPP and AMB.

Sintered metal powder processing (SMPP)

There are various metal powder combinations possible in this method. Here, the principle is to metallize the surface of the ceramic using a metal powder, with or without additives. Once metallized, the ceramic can be bonded to another using a conventional braze free of an active element such as Ag–28 wt% Cu. The dominant process is the Mo–Mn process, known as the moly-manganese process.

There are a number of ways in which the moly-manganese process can be implemented. One method is to begin with a powder slurry consisting of mixed silica glass, molybdenum and manganese to coat the surface of the ceramic. This slurry can be applied by a number of methods such as spraying, brushing or silk screening. The ceramic is then sintered at $1200\text{--}1500^\circ\text{C}$ for about 30 min in a wet hydrogen atmosphere, and then nickel plated and re-sintered at $800\text{--}950^\circ\text{C}$ in a hydrogen atmosphere for 30 min. Typically, the ratio of molybdenum powder to manganese powder is 4:1 by weight. A wet hydrogen atmosphere is one in which $p_{\text{H}_2\text{O}}$ is significant, e.g., a partial pressure of $10^2\text{--}10^3\ \text{Pa}$ or even higher.

The moly-manganese process produces a metallization layer interfaced to an outer layer of molybdenum, together up to $\sim 50\ \mu\text{m}$ thick, adhered to nickel “flash” $\sim 1\text{--}2\ \mu\text{m}$ thick. During the first sintering step, the manganese-containing components of the slurry react with the underlying ceramic to produce glassy phases within the metallization layer which bond both to the underlying ceramic and to the metallic molybdenum within the metallization layer. An example of Mo–Mn metallization is shown in Fig. 14(a); here, the metallization layer and associated nickel flash are together $< 5\ \mu\text{m}$ in thickness.

Fig. 14 (a) Mo-Mn metallization interface between Al₂O₃ and Ag-Cu eutectic braze, and (b) interface between an active metal braze and a 99.7 wt% Al₂O₃.

Table 1 Advantages and disadvantages of methods used to render ceramics wettable

	Advantages	Disadvantages
Metal hydride Vapor Deposition	Easy to apply Wide range of materials and compounds can be deposited	Difficult to produce at commercial scale Suitable equipment required
SMPP/Mo-Mn	Very reliable, high strength	Multi-step process Designed for alumina ceramics with secondary glassy phases present
AMB	Easy to use Reliable, with high strength Suitable for oxide and non-oxide ceramics	Braze spread can be difficult to control

Active metal brazing (AMB)

This process is derived from the hydride process. It was recognized that the hydrogen played relatively little part in the actual metallized layer. Instead, it was realised that the titanium component was critical and acted as an “active” element. Subsequent development of this principle has led to the development of a number of active metal brazes where the active metal is ~2–5 wt% of the total braze. Commercially, Ti is the dominant active metal in active metal brazes, but Zr and Hf are also available as active metals.

Until very recently, the moly-manganese process was the dominant liquid phase process for the bonding of engineering ceramics because of its reliability and known provenance. Its disadvantage is that it is a multi-step process requiring specialized equipment which has associated with it time and expense. Hence, over recent years, the use of active metal brazing as a liquid phase brazing process has become increasingly popular. The advantages and disadvantages to each process are summarized in [Table 1](#).

Soldering of ceramics

Soldering of ceramics can be accomplished using low melting point metals and eutectic alloys, modified either by the addition of active elements into the alloy, or by the deposition of a thin film of an active metal on the ceramics together a thin film of solder.

One group of solders are based on Sn-rich Sn-Ag-Ti alloys, which may contain 1.5–4 wt% Ti. These solders make use of the eutectic at Sn–3.5 wt% Ag at 221°C in the Sn-Ag phase diagram. Some solders have been developed for use in air. A key aspect of such technology is that the molten active solder must have its surface disrupted by mechanical means to enable wetting and bonding, because otherwise wetting is prevented by the oxidation of the surface of the solder when soldering in air. Other solders have been formulated and patented based on tin, indium, cadmium and bismuth either by themselves or in combination with tin as the majority components of the solder together with silver, an active metal such as titanium, gallium and a lanthanide such as cerium.

Fig. 15 Evolution of an alumina/Ag-Cu-Ti/alumina joint.

Brazing of ceramics

Brazes are usually referred to in terms of the main element, e.g., Ag-based brazes, Cu-based brazes and Au-based brazes. This leads naturally to a designation in terms of temperature capability. These are brazed in a vacuum atmosphere. To produce the bond the ceramic must either be metallized or an active metal used. Both the Mo-Mn metallization process and AMB are common. Typical microstructures produced are shown in Fig. 14.

The most commonly used active metal brazes are based on Ag-based alloys; these are also the most widely researched family of braze materials. The standard alloy is the Ag-28Cu (wt%) eutectic composition alloy which melts at 780°C. A reactive element such as Ti can be incorporated into the braze to produce the active metal brazes. A schematic of how the various interfacial phases produced during brazing of alumina by Ag-Cu-Ti brazes is shown in Fig. 15. In practice, the choice of time and temperature for optimal brazing of alumina to alumina using a Ag-Cu-Ti active braze is determined by having sufficient chemical reaction that there is a continuous film of both γTiO and $\text{Ti}_3\text{Cu}_3\text{O}$ formed at the Ag-Cu-Ti/alumina interface. A rule of thumb of 30°C above the liquidus temperature for 15–30 min achieves this optimal microstructure, but this can vary according to sample size. When brazing alumina to a metallic alloy such as Kovar®, Fe-29Ni-17Co (wt%), which has a similar CTE to alumina, the conditions for brazing alter because of the affinity of titanium in the braze for iron and nickel in the Kovar – the brazing temperature needs to be closer to the liquidus temperature, e.g., 10°C above, and the brazing time shorter, e.g., 5 min.

Referring to Fig. 15, the microstructural evolution is as follows: (a) Melting of the active metal braze facilitates diffusion of Ti to the surface of the sapphire. (b) $\text{Ti}_2\text{O}_{1-x}$ particles nucleate on sapphire to form a broken layer, with Al diffusing into the active metal braze. (c) $\text{Ti}_3\text{Cu}_3\text{O}$ particles nucleate on a continuous $\text{Ti}_2\text{O}_{1-x}$ layer. (d) Growth of $\text{Ti}_3\text{Cu}_3\text{O}$, primarily parallel to the sapphire surface, into a continuous layer with decomposition of $\text{Ti}_2\text{O}_{1-x}$. (e) Nucleation of γTiO between $\text{Ti}_3\text{Cu}_3\text{O}$ and the sapphire. (f) Formation of a continuous γTiO layer. Holding at the peak temperature for long periods of time results in (g), decomposition of $\text{Ti}_3\text{Cu}_3\text{O}$ and intergranular diffusion of Ti through the $\text{Ti}_3\text{Cu}_3\text{O}$ layer to facilitate rapid growth of γTiO , and finally h) a single thick continuous γTiO layer on the sapphire following complete decomposition of the $\text{Ti}_3\text{Cu}_3\text{O}$.

A variant on AMB uses high-entropy alloys, such as those based on CoFeCrNiCu; work on evaluating such alloys for joining ceramics is still very much at a preliminary stage of research.

Inorganic “ceramic” adhesives

Inorganic adhesives are usually silicate or phosphate-based binders incorporating ceramic particles, most commonly alumina, zirconia and magnesia. Such adhesives are suitable for applications where the components to be joined will only be subjected to very low levels of stress and where hermeticity is not a requirement. Their advantages are that they offer excellent chemical, electrical and high temperature resistance.

The high thermal loading encountered in most ceramic adhesive applications means that the joint design should take into account the mismatch in the CTEs between the inorganic adhesive and the materials to be bonded. Further design considerations should recognize the relatively poor shear strength of these adhesives, and also maximize the length/area of the bond line to distribute the stresses. Inorganic adhesives are solid particles suspended in a liquid matrix, i.e., a paste. A thickness of 200–500 μm is generally recommended in liquid form. After curing under a suitable applied load, this deposited thickness of adhesive should

produce a joint region 20–50 μm in thickness in service. Too thin a layer of adhesive prior to curing will inhibit uniform adhesion across the joint, while too thick a layer will result in cohesive failure within the cured ceramic adhesive. Surfaces to be joined should be etched, abraded or oxidized beforehand to ensure as good a bond as possible is produced.

Testing of Ceramic-Containing Joints

Mechanical testing provides information on the strength of a bond. Conventional tests include tensile testing, bend testing (3-point and 4-point) and shear testing. There are “standards” for testing ceramic–ceramic bonds. The most well-known and used is ASTM F19 “Standard test method for tension and vacuum testing metallized ceramic seals” which is used for testing the hermeticity of brazed joints, testing either the brazing operation or the metallization. The same samples can also be tensile tested. Samples used for this standard are shown in Fig. 16. These samples are relatively easy to produce and readily tested. Care must be taken not to introduce any stress concentration or bending when in the test rig.

An asymmetrical four-point flexure test method is described in ASTM C1469 “Standard Test Method for Shear Strength of Joints of Advanced Ceramics at Ambient Temperature”. The test method is intended for low-intermediate joint strengths. Joints with high strength should not be tested by this test method.

The mechanical testing of ceramic-containing bonds is extremely difficult and data produced must be carefully considered. This is particularly true for ceramic-to-metal combinations where the “strength” can be affected significantly by the mismatch in CTE, and therefore the contribution of residual stresses to the applied loads to failure. Consequently, it is very important to know the bond area and bond geometry when examining and comparing the strengths of ceramic–metal bonds. This is also the reason it is not feasible to create a single standard for the testing of ceramic–metal bonds. Direct comparison of mechanical test data from different studies should only be made when each test has used the same testing techniques and the same sample preparation.

In terms of non-destructive testing (NDT) there are no reliable techniques available because the critical flaw size within the interface is too small for detection. It is possible to model ceramic-containing bonds, at least at the macro scale. Most work considers the levels of strain induced on cooling from a bonding temperature. This gives a good indication of where the highest strains will be located. It also allows an effective method of assessing different joint designs. However, few models consider the effect of new interfacial reaction products.

Joint Design

There are two main obstacles to overcome when joining ceramics, particularly to dissimilar materials such as metals. The first is one of chemical compatibility, which, in general, can be controlled. The discontinuity between the atomic bonding in ceramics and metals can be microstructurally engineered, leading to the creation of a suitable interfacial chemistry.

The second major issue is that of mismatch in CTE. Most ceramics have CTEs between that of silicon carbide, $3 \times 10^{-6} \text{C}^{-1}$, and that of zirconia, $11 \times 10^{-6} \text{C}^{-1}$, whereas most metals have CTEs in the region of $13\text{--}18 \times 10^{-6} \text{C}^{-1}$. It is this CTE mismatch which is probably the single biggest hurdle in ceramic-metal joining, regardless of the process. A brazed joint between disks of silicon nitride and stainless steel is shown in Fig. 17. There is evidence from microstructural evaluation of a strong chemical bond,

Fig. 16 Test samples used for assessing brazed joints (ASTM F19).

Fig. 17 A brazed joint showing a “dome crack” in silicon nitride (ceramic) due to CTE mismatch.

Fig. 18 Various designs for interlayers to overcome CTE mismatch.

so strong that the tensile strains induced in the silicon nitride as a function of cooling from the brazing temperature have caused it to fail. The “dome crack” observed in Fig. 17 is a classic failure due to CTE mismatch.

The problem of CTE mismatch may be overcome by introduction of interlayers (or shims) up to several millimeters thick of material, usually metallic, with appropriate CTEs and elastic modulus, and then bonding via techniques such as diffusion bonding or brazing. Some very simple design concepts for interlayer containing bonds are shown in Fig. 18. Single interlayers are the simplest (Fig. 18(a)), then double interlayers (Fig. 18(b)). The best-known example of a double interlayer was undertaken to produce ceramic turbocharger rotors for the automotive industry. A natural extension of this is an infinite number of very thin interlayers, i.e., a graded structure (Fig. 18(c)). Such functionally graded materials (FGMs), like all interlayers, need to be carefully designed in terms of materials and relative thickness to the bond area. The use of a flexible interlayer has also been investigated; designs include convoluted washers and fibrous mattes (Fig. 18(d)).

Summary

The joining of ceramics, particularly to metals, is a key enabling technology for the industrial implementation of ceramics. There are several ways to control the microstructure to ensure properties at the bond line are fit for purpose, such as strength and hermeticity of the bond. However, regardless of the chemical quality of the bond, poor joint design may result in high levels of residual strain, and properties such as bond strength and reliability may deteriorate.

There are no standards for the production of bonds; for any given component or system, fitness for purpose must be determined by physical experimentation. Finite element modeling can offer some assistance in the design process.

Abrasives

Introduction

In our day-to-day life, few manufactured products in their production process escape a finishing and/or grinding operation involving abrasive materials. Whatever their origin, abrasive minerals or abrasive tools, their economic weight is huge; more than 10 B€ for the overall abrasives and around 2B€ for the abrasives minerals markets. The other way to assess the importance of such products is the number of patents published regularly; more than 50,000 per decade since the year 2000 (Nadolny, 2014). However, these patents are firstly, mainly related to abrasive tools and secondly, focused on super abrasives – around 10,000 patents per decade these last decades – as well as microcrystalline abrasive materials using sintered abrasive ceramic grains.

For scientists the difficulty will be to evaluate what will be the final performance of their abrasives grains in the numerous end user applications, knowing that such performance is a 50/50 combination between the abrasive grain and the abrasive tool; a common approach in the industrial abrasives community.

Although abrasive minerals are never studied from a detailed academic point of view, for industrial scientists there are big challenges which require scientific knowledge across a broad range of materials science such as crystallography, high temperature chemistry, surface chemistry, tribology, technical and advanced ceramic processing etc. This is what will be seen in the following part of this chapter which is based upon industrial experience of the author.

Minerals for Abrasives

An abrasive mineral is a sharp and hard material used to wear away the surface of softer, less resistant materials. Included within the term are both natural and synthetic substances, ranging from the relatively soft particles to the hardest known material; the diamond.

These natural abrasives like Quartz, Emery, garnet, flint, Zircon, Diamond are marginally used compared to synthetic abrasives produced by electro fused processes or by technical or advanced ceramic processes. Processes must be able to control first of all, crystal size, hardness and toughness, the key parameters to enhance abrasive performance, and also to allow manipulation of crystal and grain shape. Conventional synthetic abrasive grains are far away still based on alumina and silicon carbide which represent 99,9% of the annual World production around 2,500,000 tons (courtesy Imerys Fused Minerals internal source).

Abrasives grains are used in 3 different ways:

- (1) As loose abrasives without any support mainly for polishing applications.
- (2) As bonded abrasives in resin or ceramic wheels for a huge range of applications (Nadolny, 2014).
- (3) As coated abrasives applied by electrostatic process on paper or belt cloth. (see “Relevant Websites section” Abrasives and Finishing for Industrial applications/3M and see Relevant Websites section”).

For industrial applications, all minerals used for abrasive operations are placed above 8 on the Mohs hardness scale which is not satisfactory and not sufficiently accurate to predict what will be the abrasive performance of new synthetic industrial minerals. Producers use a combination of material properties such as Knoop hardness (see Fig. 1) and fracture toughness and associated to specific internal tests which are able to predict what will be the abrasive performance in targeted applications. This is a great challenge indeed, which implies that the mineral producer must have a very good knowledge of his customer application and the abrasive tools producer application as well as the end user application. This knowledge-base is good reason for some producers to be integrated; i.e., they produce minerals for abrasives and abrasive tools like Saint Gobain and 3M for example.

We will see that hardness is not only the necessary property to allow a material to perform as an abrasive. Fracture toughness, K_{1c} , brittleness and crystal structure are the three other characteristics which must be taken into account to evaluate the best candidate for abrasives. If fracture toughness, like hardness can be measured rather easily, brittleness, B , described by the following equation is more difficult to evaluate directly (Medvedovski, 2006).

$$B = \frac{Hv.E}{K_{1c}}$$

with Hv: Vickers Hardness (GPa); E: Young modulus (GPa); K_{1c} : Fracture Toughness ($\text{MPa.m}^{1/2}$)

This formula shows that toughness is a key property in reducing brittleness. As it is impossible to measure Young modulus on single mineral grain, this brittleness formula is replaced by a friability index which is a test commonly used in the abrasive world. The friability index is defined as the weight percentage going through a 250 μm sieve of 10 g of initial abrasive grain size F36, after a ball milling for 5 min with 6 steel balls of 20 mm diameter. Grain F36 (sieves between 350–710 μm , see Table 1) is a size distribution described by the FEPA norm, the European Federation of Abrasive Producers (FEPA, 2006).

Fig. 1 Knoop/Mohs Hardness data for some natural & synthetic minerals.

Table 1 FEPA grit F36; each grit in the FEPA norm has a size distribution described by the cumulative weight of powder through 5 sieves

	Sieve	Mesh	μm	weight %
F36	1	20	850	0
	2	30	600	< 25
	3	35	500	> 45
	3+4	40	425	> 65
	trough	45	355	< 3

The second test commonly used is a crush test on a single grit sieved between 500 μm and 600 μm and selected to have a blocky shape. This test measures the Compressive Fracture Force (CFF value expressed in Newton) required to break a single grit under an automatic press developed originally by the German company Vollstaedt-Diamant GmbH for quality control of diamonds (Vollstaedt *et al.*, 2003; List *et al.*, 2020). Associated with hardness and toughness, the friability index and the CFF value, which is an average value coming from several hundred crushed single grit, give a very good information about the effect of chemical composition and microstructure. Fig. 2 gives an overview of how these two characteristics relate to physical and chemical properties of materials. Clearly, the sintered materials lead to higher CFF values and a lower friability index.

For abrasive applications, like for ceramics, microstructure is a key parameter. Finer is, better. However, for abrasives the final performance comes from the right balance of hardness/toughness and CFF/friability. Only synthetic minerals can offer such possibilities.

Let's take crystal size as a key to describe the abrasive evolution.

Figs. 3 and 4 show such an evolution to increase abrasive performance. However, it's important to keep in mind that up to now more than 90% of industrial minerals are produced by electro fused processes despite the limit of this process for producing materials with a fine microstructure.

Electro Fused Abrasives

Around 2,000,000 tons/year of alumina (60%) and SiC (40%) are produced using the arc furnace technology known since beginning of twentieth century for the production of ferroalloys and steels. The production of the corundum abrasive family is described Fig. 5.

Raw materials for this process are typically:

- (1) Alumina powder for direct fusion to convert this alumina powder into alumina coarse crystal after cooling and crushing. A low addition of Cr gives either pink or ruby corundum.
- (2) Alumina + Baddeleyite powder to get fused alumina with 25% or 42% ZrO₂ which is the eutectic composition for Al₂O₃/ZrO₂ and has a dendritic microstructure. For these two compositions the cooling step is a key one (Marlin *et al.*, 2011; Fischer *et al.*, 2012) which requires a fast solidification as we will see.

Fig. 2 CFF value and Friability index of main synthetic abrasive minerals.

Fig. 3 Process evolution vs. elementary crystal size from electro fused to Sol-Gel processes.

Fig. 4 Crystal sizes obtained from electro fused to sol gel abrasive minerals.

- (3) Bauxite + carbon for a carbo-reduction fusion to produce corundum with different level of Ti. 2%–3% for regular brown and 1%–1.5% for brown semi friable.

These different alumina compositions cover a wide range of abrasive applications.

Table 2 is an overview of the characteristics of such minerals for abrasive applications. All producers supply such types of fused products. (see web sites see “Relevant Websites section”; see “Relevant Websites section”; see “Relevant Websites section”).

They operate with arc furnaces of 2–10 MW power to produce ingots of 10–20 tons following a batch process. In a 4 MW arc furnace 10–12 tons of alumina are melted in 3 h and poured as fast as possible in a crucible to avoid solidification in the casting channel. Regarding the alumina’s refractoriness, the ingot surface solidifies immediately but a full week is required to cool it down totally before the next step. Thus, there is a very low solidification step leading to the abrasive grains after crushing, milling and sizing into FEPA grit sizes. Finally the electro fused abrasive grit can be considered as a single crystal having shapes and densities designed by the process steps mentioned in **Fig. 5**.
